Southern (American) Hospitality:

Italians in Argentina and the US during the Age of Mass Migration

Santiago Pérez[*]

June 11, 2019

Abstract

Italians were the largest contributors to the rise in southern European immigration that took place in the US at the turn of the 20th century. This rise fueled anti-immigrant sentiments which concluded with the US abandoning its open-door policy for European immigrants. I study the selection and economic outcomes of Italians in Argentina and the US, the two largest destinations for Italians in this period. Prior cross-sectional work shows that Italians had faster assimilation in Argentina, but is inconclusive on whether this was due to differences in selection or to differences in host-country conditions. I assemble data following Italians from passenger lists to population censuses, enabling me to compare migrants with similar regional origins and pre-migration characteristics. First- and second-generation Italians had better economic outcomes in Argentina. Observable pre-migration characteristics cannot explain these differences. Path dependence in migration flows can rationalize these differences in an era of open borders.

1 Introduction

At the turn of the 20th century, the shift in migrants' region of origin toward Southern and Eastern Europe fueled the rise of anti-immigrant sentiments in the US. In 1907, the US Congress convened a special commission to analyze the social and economic life of immigrants. The *Immigration Commission* painted a dismal picture of Italians, the largest contributors to the surge of southern European immigration: Italians were consistently at the bottom in terms of family income, rates of home ownership and job skills (Dillingham, 1911). The conclusions of the Commission served as the basis for the imposition of country of origin quotas, which in 1924 limited the number of Italian arrivals to just 4,000 per year.

The situation of Italians in the US contrasts with their situation in Argentina, the second largest destination for Italians during the age of mass migration. For instance, in 1909 Italians owned 38 percent of the 28,632 commercial establishments of Buenos Aires, despite them being just 22 percent of the city's population (Martínez, 1910). According to Klein (1983, p. 306), "the sharp differences in the Italian immigrant experience within Argentina and the United States were fully perceived by both the immigrants themselves and virtually all contemporary observers."

The reasons for these differences are however less clear: Were the Italians who went to Argentina better prepared for the migration experience than those who went to the US? Or did they encounter a more welcoming host society?[1] Existing comparative studies on the economic assimilation of Italians in the Americas are based on cross-sectional data from the receiving countries, such as censuses of population. These data make it hard to tease out these different explanations. For instance, a well-known difference between Italians in Argentina and the US is that Argentina attracted a higher fraction of northern Italians (Klein, 1983). However, neither Argentine nor US censuses include information on the regional origins of Italians.

I study the selection and economic outcomes of Italians in Argentina and the US during the age of mass migration. To do so, I assembled data following Italian immigrants from passenger lists to censuses of population. In these data, I observe the year of entry, port of origin and pre-migration occupation of a sample of Italians who resided in Argentina or the US by the late 19th century.

---

[1]Here I paraphrase Baily (1983, p. 295), who asked: "Were the Italians in Buenos Aires in some way better prepared for the immigration experience than those who went to New York? Did they encounter a more receptive host society?"

These data enable me to assess the extent to which pre-migration characteristics can explain the differences in economic outcomes at the destination countries.

Beyond its historical significance, studying migrants' destination choices and their subsequent assimilation in this era can inform broader issues on the economics of immigration. Neoclassical models of migration predict destination choices to depend mainly on wage differentials between the origin and the potential destinations (Sjaastad, 1962; Todaro, 1969). On the other hand, network theories of migration emphasize the strength of migrants' networks abroad as the key driver of destination choices (Massey, Arango, Hugo, Kouaouci, Pellegrino, and Taylor, 1993). Distinguishing these theories in modern datasets is complicated because migration policy interferes with migrants' decisions (Beine et al., 2011). For instance, current US migration policy explicitly favors "network" migration through family reunification visas. In contrast, in the historical episode that I study, both Argentina and the US maintained nearly open borders for European immigration.

I start by comparing Italians in the census cross sections of 1895 Argentina and 1900 US. I focus on two main economic outcomes throughout the analysis: a person's occupation and whether he owned his home at the destination country. Consistent with the historical literature (Baily, 1983; Klein, 1983; Baily, 2004), I document that Italians in Argentina had higher rates of home ownership and were more likely to hold skilled occupations than Italians in the US. Italians in Argentina outperform those in the US also when compared to the native born in their respective countries.

The advantage of Italians in Argentina relative to Italians in the US might have been driven by differences in the characteristics of those moving to each of the countries. I use individual-level passenger lists data to compare the pre-migration characteristics of Italians moving to Argentina or the US before 1900. The main difference between both groups was the higher fraction of Italians departing from northern ports among those going to Argentina. However, I find small or no differences in other demographic characteristics and in pre-migration occupations: Italians who moved to Argentina or the US were similar with respect to their age and gender structure, and were employed in similar (predominantly unskilled) occupations prior to migrating.

I next compare the economic outcomes of Italians in Argentina and the US using the linked passenger lists to census data. Here, I am able to narrow the comparison to immigrants who left Italy in the same year, from the same port and who had the same pre-migration occupation and

literacy level. The advantage of Italian migrants in Argentina is in most cases similar to that in the cross section. This similarity suggests a limited role for observable pre-migration characteristics (including regional origins within Italy) in explaining the advantage of Italians in Argentina.

As a last exercise, I further narrow the comparison to Italian immigrants who shared a surname but moved to different destinations. This comparison serves two purposes. First, Italian surnames are informative of regional origins (Guglielmino and De Silvestri, 1995; Spitzer and Zimran, 2018). Hence, surnames enable me to absorb a finer regional variation than the one captured by ports of origin. Second, Clark, Cummins, Hao, and Vidal (2015) and Güell, Rodríguez Mora, and Telmer (2014) show that there is substantial persistence in economic outcomes across family lines, an effect that a within-surname comparison would absorb. These results show a similar pattern, again suggesting a limited role for pre-migration characteristics in explaining the outcomes of Italians in the Americas.

How persistent were these differences by the second generation? To answer this question, I compare the outcomes of native-born children of Italian immigrants in Argentina and the US. Second-generation Italians in the US continued to be less likely to own property and hold a skilled occupation than children of Italians in Argentina. However, I find a smaller gap in the likelihood of holding a skilled occupation, suggesting some convergence at least in this dimension.

Which host-country conditions explain the differences in economic outcomes? First, I show that despite Italians in Argentina and the US had similar levels of human capital (as proxied by literacy and numeracy rates), Italians in Argentina had higher levels of human capital *relative* to the native born. Second, I find evidence consistent with the closer linguistic distance between Italian and Spanish enabling Italians to enter a broader set of occupations in Argentina than in the US. Specifically, Italians in Argentina were more likely to enter non-manual occupations, suggesting that a lack of English ability was a barrier for Italians in the US. Finally, I provide qualitative and historical survey evidence showing the widespread prejudice against Italians in the US during this time period.

The analysis is based on a sample of individuals who chose to stay in the Americas (at least until the time of the censuses). However, a substantial fraction of Italians (both in Argentina and the US) eventually returned to Italy during this era (Bandiera, Rasul, and Viarengo, 2013). One hypothesis in the historical literature for the better performance of Italians in Argentina is that

4

Italian migrations to the US were less likely to be permanent, thus reducing the incentives to invest in host-country specific human capital. Indeed, the US Immigration Commission pointed to the high rates of return migration among southern Europeans as one of the main reasons for their lack of assimilation, and even recommended restricting temporary migrations.[2] My results provide evidence against this explanation, as the advantage of Italians in Argentina was present even by the second generation. Moreover, rates of return migration were actually similar for these cohorts of Italians in Argentina and the US.

The large differences in economic outcomes and the likely limited role of pre-migration characteristics pose a puzzle: Why did (in an era of open borders) some Italians choose a country that offered them limited prospects for upward mobility? One potential explanation is that, despite upward mobility was lower, wages for unskilled workers were higher in the US than in Argentina. Hence, Italians deciding between Argentina and the US might have faced a trade-off between higher wages in the short-term and higher long-term prospects for upward mobility. However, the fact that Italians in Argentina and the US had similar arrival ages and rates of return migration is not entirely consistent with this explanation.

An alternative explanation is that immigrant networks generated path dependence in destination choices: For Italians choosing where to migrate, having relatives or friends in one of the destinations might have been the decisive factor. In the last part of the paper, I use the passenger list data to test whether migrants were more likely to move to the destination to which their "family and friends" had migrated in the past. Because I do not directly observe family or friendship relationships among immigrants, I use the surnames of previous migrants to Argentina and the US to construct a proxy for the size of a migrant's network at each potential destination. I find that this measure is a strong predictor of where Italians moved, suggesting a role for path dependence in explaining destination choices. Consistent with network effects, the measure has stronger predictive power for women, children and for relatively unskilled migrants.

This paper is related to the literature on immigrant assimilation during the Age of Mass Migration. Several papers have studied the economic assimilation of immigrants in specific receiving countries. For instance, Abramitzky, Boustan, and Eriksson (2014), Catron (2016) and Ferrie

---

[2] "As far as possible, the aliens excluded should be those who come to this country with no intention to become American citizens or even to maintain a permanent residence here, but merely to save enough, by the adoption, if necessary, of low standards of living, to return permanently to their home country." (Dillingham, 1911)

(1994, 1997) study the assimilation of immigrants in the US, whereas Inwood et al. (2016) and Green and MacKinnon (2001) study the case of Canada.[3] In previous work (Pérez, 2017), I studied the economic assimilation of European immigrants in 19th-century Argentina. However, no quantitative studies have looked at the *comparative* performance of immigrant groups across different receiving countries. The case of Italian migration to Argentina and the US is especially relevant, as it deals with the main sending country and the two largest destinations during this time period. Italians are also an ideal case study because they migrated in large numbers to both North and South America, and because of the availability of individual-level data with information on pre- and post-migration outcomes.[4]

2 Italian Mass Emigration

From 1876 to 1915, more than 14 million Italians migrated to other countries in Europe and to the Americas. Italians represented the largest flow in absolute numbers during the age of mass migration. In per capita terms, Italian emigration rates were only second to the Irish (Taylor and Williamson, 1997).

The Italian case was distinct from that of other European countries in that Italians emigrated in large numbers to multiple destinations: about 60% moved to South and North America, and the rest moved to other countries within Europe. Argentina and the US were the two largest destinations for the transcontinental flow, receiving 2.5 and 4.5 million Italians from 1857 to 1924, respectively (Ferenczi, 1929). Figure 1 shows the yearly number of Italian arrivals to Argentina and the US in this period. While Italians were more likely to migrate to Argentina than to the US from 1860 to 1880, both countries attracted similar numbers during the last two decades of the 19th century. After 1900, however, the majority of Italian migration was directed towards the US.

The increase in migration to the US relative to Argentina coincided with a change in the regional origins of Italian migrants. During the second half of the 19th century, Italian emigration was more predominant in the relatively more developed north of the country. By the turn of the 20th century,

---

[3]Other examples include Hatton (1997) and Minns (2000) for the US, and Moya (1998) for Argentina.

[4]Italians are the only immigrant group for which there was significant overlap between Argentina and the US. The second largest sending country for Argentina was Spain: Italy and Spain combined account for more than 80% of all the immigrants who went to Argentina. However, there were only about 7,000 Spanish immigrants in 1900 US (Gibson and Jung, 1999).

southern Italian migration took off (Gomellini and O'Grada, 2011). As I will show below, northern Italians were overrepresented among those moving to Argentina.[5]

3   Data

I use two sources of individual-level data for Argentina and the US: passenger lists of immigrant arrivals and censuses of population. The Argentine passenger lists were originally collected by Argentina's National Direction of Immigration and have been digitized by the *Centro de Estudios Migratorios Latinoamericanos* and *Fondazione Rodolfo Agnelli*. The data include about 1,020,000 records of Italians who arrived to Argentina through the port of Buenos Aires between 1882 and 1920.[6] Each record contains the name, age, sex, civil status, literacy, occupation, date of arrival and port of origin of each passenger on the ship. Other than port of origin, the data do not include any systematic information on last place of residence within Italy.

The US passenger lists come from the National Archives ("Italians to America" passenger data file) and are based on information collected by the US Customs Service. The data include about 845,000 passengers who arrived to the US between 1855 and 1900, and who identified their country of origin as Italy or one of the following regions: Lombardy, Piedmont, Sardinia, Sicily, or Tuscany. Most of the records are of passengers arriving to New York, although other US ports are also included. Each record contains information on name, age, sex, literacy, occupation, town of last residence, destination within the US, date of arrival, port of origin and entry and class of travel of each passenger of the ship.

I linked males in these passenger lists to national censuses of population of Argentina and the US. In the case of Argentina, the 1895 census is the only census for which such linking is possible, since the previous national census (which took place in 1869) was conducted before the passenger list data started being systematically collected, and there are no surviving individual-level records for the next census (which took place in 1914). For the US, I linked the passenger lists to the 1900 census, as this is the closest in time to the 1895 Argentine census (there are no surviving individual-level records of the 1890 US census). To improve the comparability between the Argentine and US

---

[5]Northern Italians were also overrepresented among those going to Brazil. Klein (1989) shows that the economic outcomes of Italians in Brazil were similar to those of Italians in Argentina.

[6]About 75% of immigrants entered Argentina through the port of Buenos Aires in this time period (de Inmigración, 1925). I discuss the coverage and representativeness of the passenger list data in online appendix section A.1.

data, I restricted the US sample to arrivals on or after 1882. Note that, as a result of these data limitations, my analysis excludes Italians who arrived during the peak of Italian immigration to the US (after 1900).

The linking is based on country of birth, first and last name, and reported age. A challenge in linking these data is that some Italians declared their original name (in Italian) upon arrival but later adopted a Spanish/English version of it (see Biavaschi et al. (2017) and Carneiro et al. (2017)). For instance, the *Giuseppes* were likely to become *Josés* in Argentina and *Josephs* in the US. To deal with this challenge, I first used a dictionary of names to translate Italian names into their Spanish or English counterparts. Then, I used these translated names as an additional input in the linking procedure, following a similar procedure as in Alexander et al. (2018) and Pérez (2017).

To link individuals from the passenger lists to the censuses, I implemented the following linking procedure (described in detail in Abramitzky et al. (2019)). In the first step, I identified a group of individuals in the passenger lists that I would attempt to match to the census. I then searched the census for a set of potential matches for each of these individuals. I identified potential matches as individuals who: (1) reported Italy as their place of birth, (2) had a predicted age difference of no more than five years in absolute value, and (3) had first and last names starting with the same letter. Based on the similarity of their reported names and predicted years of birth, I calculated a linking score ranging from 0 to 1 for each pair of potential matches, with higher scores corresponding to pairs of records that were more similar to each other.[7]

To be considered a unique match for an individual in the passenger lists, a record in the census had to satisfy three conditions: (1) being the record with the highest linking score p_1 among all the potential matches for that individual, (2) having a linking score above a threshold ($p_1 > \underline{p}$, with $\underline{p} \in (0,1)$), and (3) having a linking score sufficiently higher than the second highest linking score ($p_2 < l$, with $l \in [0, \underline{p})$). In the baseline analysis, I only kept observations with a linking score of at least 0.7 and a second highest linking score of at most 0.5. In section 4.4, I show the robustness of the results to using more conservative choices of the linking parameters.

An important concern with using such data is that some of the links might be incorrect (Bailey

---

[7]To measure similarity in first and last names, I used the Jaro-Winkler string distance function (Winkler, 1990), whereas to measure similarity in ages I used the absolute value of the predicted years of birth.

et al., 2017). A high fraction of incorrect matches would result in pre-migration characteristics being measured with substantial error, thus mechanically reducing the predictive power of such variables. To address this concern, I chose a relatively conservative set of linking parameters. While this choice implies that I am able to uniquely match a relatively small fraction of records (due to a standard trade-off between type I and type II errors), it also implies that the quality of matches is likely higher. Indeed, Abramitzky et al. (2018) show that this method achieves low rates of false positives (below 5%) when choosing conservative linking parameters, although at the expense of matching relatively few observations. In this case, using my baseline parameters I uniquely link around 6% of the Argentine observations and 4% of the US observations. Lower matching rates for the US are expected given slightly higher return migration and the fact that Italian names in the US were probably more likely to be misspelled than in Argentina (given the similarity between Italian and Spanish).[8] In the robustness section of the paper, I also show that the results are robust to imposing an even higher threshold for considering an observation as a match.

An additional concern is whether this linking procedure generates representative samples. Tables A1 and A2 compare immigrants in the passenger lists who were uniquely linked to the census to those who were not. To do so, I estimate a probit model of the likelihood of being linked to an observation in the census as a function of observable characteristics upon arrival, separately for the Argentina and the US data. The tables report the probit marginal effects for each of the included characteristics.

There are some statistically significant differences between Italians in the passenger lists and those in the linked data, although the differences are in all cases quite small. Both in the Argentina and US samples, I am less likely to match individuals who report an unskilled occupation upon arrival. There is also a small correlation between age upon arrival (positive for Argentina, negative for the US) and the likelihood of matching. It is also worth noting that immigrants in the linked sample might differ from immigrants in the passenger lists data for reasons unrelated to the linking procedure (for instance, selective mortality or return migration). In section 4.4, I show that the results are similar when I reweight the data to account for selection with respect to these observable characteristics. Also, whenever possible, I show results based on the cross-sectional data (which

---

[8] When comparing two independent transcriptions of the 1940 US census, Abramitzky et al. (2018) show that Italian surnames have very high rates of discrepancies: 32% of the surnames have at least a one character difference.

does not rely upon linking).

Both the US passenger lists data and the US 1900 census are fully digitized, including the information on occupations and other economic outcomes. The Argentine passenger lists are also fully digitized, but only the *indexes* of the 1895 census are. Hence, after linking the data, I manually digitized the economic information in the 1895 Argentine census (using the original manuscripts available in the genealogy website familysearch.org). The baseline linked samples include about 15,000 observations for Argentina and about 15,000 for the US.

4   Results

4.1   Differences in the cross section

I start by comparing Italian immigrants in the Argentine and US census cross-sections of 1895 and 1900, respectively. To do so, I use the sample of Italians to estimate the following model:

$$y_{ic} = \alpha + \beta Argentina_{ic} + \gamma X_i + \epsilon_{ic} \tag{1}$$

where y_{ic} is an economic outcome of individual i in destination country c. Throughout the analysis, I focus on two outcomes that can be consistently measured in the Argentine and US censuses: the likelihood of home ownership and the likelihood of holding an unskilled occupation. To classify occupations into occupational groups, I first assigned each occupation an HISCO code, which I then mapped into occupational categories using the Historical International Social Class Scheme (HISCLASS) (Leeuwen et al., 2002). This classification is based on the International Standard Classification of Occupations (ISCO) and has been adapted to deal with historical data.[9]

The coefficient of interest is β, which measures the economic advantage/disadvantage of Italians in Argentina relative to Italians in the US. The Argentine data are from the sample of the 1895 census compiled by Somoza (1967), and the US data are from IPUMS (Ruggles et al., 1997). The sample is restricted to males aged 18 to 60 years old at the time of the census. In all specifications, I control for an individual's age using fixed effects (captured by the vector X_i).

---

[9]Unskilled jobs are those in HISCLASS categories 10 to 12. The 1895 Argentine census asked *"¿Posee propiedad raíz?"* ("Do you own real estate property?"). The 1900 US census asked "Is the person's home owned or rented?". Neither the 1895 Argentine nor the 1900 US censuses contain information on individual-level earnings, which prevents me from looking at earnings as an outcome variable.

One issue with this model is that the Italian advantage/disadvantage in Argentina might just reflect aggregate differences between the Argentine and US economies rather than Italian-specific differences. Indeed, Klein (1983) argues that differences in the structure of the labor markets of Argentina and the US played a role in explaining the differences between Italians in both countries. Specifically, his argument is that the preponderance of small artisan shops in Argentine manufacturing offered more opportunities for skilled blue-collar and white-collar jobs than the more industrialized US economy.

Hence, I also estimate a model measuring whether Italians in Argentina did better/worse than Italians in the US relative to natives in their respective countries. I estimate:

$$y_{ic} = \alpha_0 + \beta_1 Italian_{ic} + \beta_2 Argentina + \beta_3 Italian_{ic} \times Argentina_{ic} + \gamma X_i + \epsilon_{ic} \qquad (2)$$

Here, the coefficient of interest is β_3 which measures the advantage/disadvantage of Italians in Argentina relative to Italians in the US, net of aggregate differences between both destination countries.

Table 1 shows that first-generation Italians in Argentina were 4 percentage points more likely to own their home, relative to a baseline of 14.4 percent among Italians in the US. The relative advantage of Italians in terms of home ownership is much larger (above 25 percentage points) when including the native born of both countries in the sample. Italians in Argentina were also 28 percentage points less likely to be employed in an unskilled occupation, relative to a baseline of about 50 percent among Italians in the US. This gap is very similar when including the native born in the sample.

4.2 Differences in selection

The above results confirm the relative economic success of Italians in Argentina documented in Klein (1983) and Baily (1983, 2004). In addition, they indicate that the advantage of Italians in Argentina was also present when measured relative to natives in both receiving countries.

However, the relative advantage of Italians in Argentina might have just reflected differences in the pre-migration characteristics of those who went to each of the countries. For instance, Argentina received relatively more migration from the north of Italy (which was already more developed than

the South at the time (Federico et al., 2019)) than the US. Figure 2 shows the ten largest ports of origin of Italian arrivals to Argentina and the US in the 1882-1900 period. Genoa and Naples were the two largest ports of departure of Italian migrants, both for Argentina and the US. However, while close to 80% of the Italians entering Argentina departed from the port of Genoa (a northern port), less than 20% of those moving to the US did so. In contrast, Naples (a southern port) accounted for more than half of arrivals to the US, but for only 10% of the arrivals to Argentina.

Whether Argentina received relatively more skilled migrants than the US is controversial in the historical literature. On the one hand, Baily (1983, p. 295) argues that "Those who migrated to Buenos Aires included more workers with higher levels of skill and of literacy, more individuals with experience in organization, and more people who intended to stay." On the other hand, Klein (1983, p. 329) argues that: "No significant factors in the Italian origin of the immigrants, or in their cultural make-up, can as fully explain the social and economic history of the Italians in the Americas."

I next use the passenger lists data to compare the pre-migration characteristics of Italians arriving to Argentina and the US. For this analysis, I use the data on 1882 to 1900 arrivals, as these are the years for which the Argentine and US passenger lists overlap. Specifically, I estimate:

$$x_{it} = \alpha + \beta Argentina_{it} + \gamma Z_{it} + \epsilon_{it} \tag{3}$$

where x_{ict} represents a pre-migration characteristic of immigrant i arriving in year t.

Table 2 shows the results of these regressions, where each row represents a different individual-level characteristic. In the first column, I report the average value of each of these variables in the US data. In the remaining columns, I report the value of β (the Argentina-US difference) as I progressively net out year of arrival and port of origin fixed effects (captured by the vector Z_{it} in equation 3).

The top panel compares Italian migrants in Argentina and the US with respect to demographic characteristics: the fraction of males, average age and the fraction of children (defined as those aged 16 or less). These variables are important because a higher fraction of women and children is indicative of the prevalence of family migration and hence, of the intended permanency of migrations.

In the raw data, Italians moving to Argentina were on average younger, more likely to be aged less than 16, and less likely to be male. However, this pattern reverses once I include year of entry and port of origin fixed effects, thus comparing Italians moving to the Americas on the same year and from the same port. Overall, even in the raw data, there were no large differences in the age structure and gender ratios of Italians moving to Argentina or the US: both groups were largely comprised of working-age males, with males aged 18 to 60 years old accounting for close to 60% of the flow in both cases. Figure B1 in the Online Appendix shows that the overall age structure of both groups (and not just the average age) was also very similar. This figure uses the pooled 1882-1900 data to plot a histogram of the ages of Italians arriving to Argentina or the US.

I next look at differences in pre-migration occupations. Here, I focus on the sample of males aged 18 to 60 years old upon arrival. Italians who went to Argentina were overrepresented among those holding white-collar jobs (although the proportion of workers in this category was fairly small in both flows at around 3%), and underrepresented among those holding skilled/semi-skilled jobs. The differences in this regard are of similar magnitude when including the various fixed effects.

The most salient difference in terms of pre-migration occupations is that Italians who migrated to Argentina were more likely to report farming and less likely to report unskilled occupations. Part of this difference captures differences across regions of origin: including port of origin fixed effects reduces the Argentina-US difference in the likelihood of holding a farming occupation from 20 to 13 percentage points.

However, as discussed in the historical literature, the distinction between farm and general laborers is unlikely to have been very informative in this context: As late as 1911, about 60% of the Italian workforce was still employed in agriculture.[10] Indeed, the linked data enable me to explicitly test the informativeness of the distinction between general and farm laborers. Specifically, if this distinction captured some relevant information, we should observe differences in the outcomes at the destination of both types of workers. Yet, when using the linked data in section 4.3, I find that whether an individual declared a farming or an unskilled occupation upon arrival has little

---

[10]For instance, Klein (1983, p. 313) writes that "the entire distinction between non-farm unskilled laborers and farm workers may have been rather artificial." Coletti (1912) declared that he and all other analysts of Italian emigration have found that "laborers, day laborers, and the like come in large part from the rural classes and for that reason should be added to the category of agricultural laborers in order to account fully for the rural contingent in the emigrant stream."

predictive power on his outcomes at the destination.[11]

Literacy is another measure of skills that was collected in the passenger lists. Unfortunately, this variable is missing for about 60% of the individuals in the US data. One way to deal with this limitation is to measure literacy in the census cross sections of 1895 Argentina and 1900 US: 64% of the Italians aged 18 to 60 in 1895 Argentina were literate, compared to 59% in 1900 US% (own calculation based on Somoza (1967) and Ruggles et al. (1997)). So, while Italians in Argentina were more likely to be literate, the difference was not very large.[12] Indeed, the difference is much smaller than the difference between southern and northern Italians who remained in Italy: by 1901 only 30% of southerners were literate, compared to 65% of northerners (Klein, 1983).

In settings in which other measures are unavailable, age heaping –the tendency of individuals to report "attractive" numbers as their age, typically multiples of five– has been used as a proxy for quantitative skills. A'Hearn et al. (2009) show that, when age heaping and literacy are both observed, there is a high correlation between the two.[13] To test whether Italians moving to Argentina had higher numeracy (as proxied by age heaping), I define an indicator that takes a value of 1 if an individual reported an age with a multiple of five as its last digit. The table shows that Italians in Argentina were slightly less likely to report a multiple of five as their age, but that this difference is very small in magnitude.[14]

Overall, the above analysis indicates that the main difference between Italians who moved to Argentina and those who moved to the US was their region of origin, with smaller or no differences in other pre-migration characteristics. However, one limitation of the analysis is that the available measures of skills are all relatively coarse. Spitzer and Zimran (2018) use the heights of Italians

---

[11]Ferrie (1997) makes a similar point regarding the distinction between farmers, farm tenants and unskilled workers in the US passenger lists of the mid 19th century. He writes: "Farmers are more problematic. This is probably less the result of carelessness on the part of those compiling the lists than it is the result of the presence of large numbers of farm tenants in Europe and the absence of the term "tenant" in the ship lists. An individual who was a farm tenant in Europe would thus have been described as either a farmer or a laborer in the ship lists. Since there were no clear guidelines by which farm tenants were assigned to either group in the ship lists, we cannot separate those who were farm tenants in Europe (who were probably more akin to laborers in the amount of capital they possessed and the amount of supervision they received) from independent farmers. The same problem applies to a lesser degree for those reported as unskilled in the ship lists."

[12]Also, note that differences in the cross sectional data might exaggerate differences upon arrival if Italians were more likely to accumulate skills while in Argentina.

[13]In the census data described above, there is also a negative correlation between being literate and the likelihood of reporting a multiple of five as age.

[14]A number of studies use this measure in the context of immigration. Mokyr and Grada (1982) use this measure to analyze the selection of Irish famine migrants. Stolz and Baten (2012) use this measure to test whether immigrant selection responded to relative inequality. Collins and Zimran (2018) use it to study the selection of Irish famine immigrants.

entering the US to study immigrant selectivity. They find that migrants moving to the US were positively selected *within* their provinces of origin, but negatively selected overall.This pattern is also consistent with the fact that, despite there were large differences in literacy rates between the South and the North and that Argentina attracted more Northerners, the literacy rates of Italians in Argentina and the US were close to each other. Unfortunately, the Argentine authorities did not collect systematic data on heights that would allow me to compare Italians in Argentina and the US with respect to this characteristic.[15]

4.3 Differences in the linked data

Italians who moved to Argentina were more likely to be northerners, but there were no large differences in other observable characteristics, including pre-migration occupations, literacy and proxies for numeracy. How much of the relative advantage of Italians in Argentina can be explained by these differences in pre-migration characteristics? To answer this question, I use the data linking passenger lists to the Argentine and US censuses.

I start by constructing occupational transition matrices, in which rows represent an immigrant's occupation in Italy, and columns represent his occupation in Argentina or the US. Panel (a) in Table 3 shows this transition matrix for Argentina, whereas panel (b) shows the corresponding matrix for the US. Despite Italian migrants were predominantly from rural backgrounds, they concentrated in urban areas in both Argentina and the US, particularly in the port of entry cities of Buenos Aires and New York. Indeed, a relatively small fraction (about 20%) of Italians in Argentina and the US worked as farmers (last row of each transition matrix). The majority of Italians in the US were employed as unskilled workers, whereas the largest category for Italians in Argentina was that of skilled/semi-skilled workers. Relative to Italians in the US, Italians in Argentina were also more likely to be employed in white-collar jobs.

Turning to the occupational transitions, Italians in Argentina were less likely to experience occupational *downgrading* than Italians in the US. For instance, among Italians with a white-collar job in Europe, only 12% held an unskilled occupation in Argentina. In contrast, among Italians in the US, the chances of landing an unskilled job were substantial (36%) even for those previously

---

[15]Kosack and Ward (2014) use heights to measure the selectivity of Mexican migration to the US in the early 20th century.

employed as white-collar workers. Moreover, the likelihood of moving out of unskilled occupations was lower in the US (42%) than in Argentina (77%).

In the last row of the table, I simulate the occupational distribution of Italians in the US, had they been exposed to the transition matrix of Italians in Argentina, following the approach in Collins and Wanamaker (2017). This counterfactual distribution is quite different from the observed one for Italians in the US. For instance, while more than half of the Italians in the US worked in unskilled jobs, the counterfactual fraction of unskilled workers is just 20%. In addition, the counterfactual distribution for Italians in the US is very close to the observed one in Argentina, which is consistent with the fact that the occupations upon arrival were similar for both groups (as documented above).

In Tables B1 and B2, I split Italians into those departing from southern and those departing from northern ports, respectively. Only for the purposes of this exercise, I exclude Italians departing from non-Italian ports. The tables show no large differences between the occupational distribution of southern and northern Italians in neither Argentina nor the US. Similar to the results above, there is a lower fraction of workers in unskilled occupations in the counterfactual occupational distribution, both for southern and northern Italians.

I next estimate versions of equation 1 in which I include pre-migration characteristics as control variables. Table 4 shows the results of this exercise. In panel (a), I focus on the likelihood of home ownership, whereas in panel (b) I focus on the likelihood of holding an unskilled job. The first column of each panel (which does not include any controls other than age fixed effects) shows a similar pattern to the cross-sectional results in Table 1: Italians in Argentina were 5.6 percentage points more likely to own their home and 25 percentage points less likely to hold an unskilled occupation.

In the second column, I add indicator variables based on the number of years spent in each of the countries. Adding this variable slightly reduces both coefficients in magnitude (reflecting that Italians in Argentina had on average spent more years at the destination by the time of the censuses), but the overall pattern is similar. Figure 3 shows the relationship between time spent in each of the countries and outcomes at the destination, net of age fixed effects. With just one cross-section of data, I cannot disentangle cohort effects from years since migration.[16] Yet,

---

[16] An added difficulty is that the census data are from two different points in time in the two countries (1895 and

16

the data suggest that, in both countries, a longer stay was associated with a higher likelihood of home ownership and a lower likelihood of holding an unskilled job. Also, the figure suggests little convergence between Italians in Argentina and those in the US.

In the third column, I further absorb the port of origin of each migrant. This specification enables me to test if the different mix between northern and southern Italians in Argentina and the US could explain their different outcomes at each of the destinations. This variable makes a difference in the home ownership results (where the coefficient declines by about a third), but makes little difference in the likelihood of holding an unskilled job. The results are nearly identical if I restrict the sample to include only immigrants who departed from Italian ports (Table B3 in the Appendix). In Table B5, I split Italians into four mutually excluding groups based on whether they departed from a southern or a northern port, and whether they migrated to Argentina or the US. The table indicates that both North and Southern Italians did better in Argentina than in the US with respect to home ownership and the likelihood of holding an unskilled occupation. In addition, both in Argentina and the US, the results indicate an advantage of Northern over Southern Italians.

In column 4 of Table 4, I include indicators for the occupational category declared upon arrival and for literacy (as reported in the census). Adding these variables increases the predictive power of the regressions (as reflected by the R-squared), but has relatively little impact on the estimated coefficients on both outcome variables. This pattern is not surprising given the balancing in these characteristics documented above.[17]

In column 5, I include surname fixed effects, thus comparing two Italian immigrants with the same surname but who moved to different destinations. Because of errors in transcribed surnames, I use a phonetically equivalent version of surnames based on NYSIIS, although preserving the last letter of the original surname (as the last letter of a surname is a strong predictor of regional origins in the Italian case).[18] There are two reasons why surnames might provide information beyond the one contained in the other observable characteristics. First, Italian surnames are informative of

_____

1900).

[17]One concern with this exercise is that, as discussed above, the passenger lists data is likely not entirely accurate in distinguishing farmers from unskilled workers. To address this issue, in Table B4 I reestimate this specification while excluding from the sample everyone who reported either farming or an unskilled occupation.

[18]Not doing so would result, for instance, in assigning the same surname to migrants whose original surnames were "Russo" or "Rossi".

regional origins within Italy (Spitzer and Zimran, 2018). Hence, exploiting within-surname variation enables me to net out differences in the region of origin of migrants beyond those captured by ports of origin. A further advantage of surnames is that they provide a measure of region of origin that does not depend on accurately linking the passenger lists to the census. Second, Clark et al. (2015) and Güell et al. (2014) highlight the persistence in a variety of outcomes across family lines. The findings of these studies suggest that surnames might also capture differences in broadly defined social status beyond those captured by occupations.[19]

This specification requires overlap between the surnames of immigrants who moved to Argentina and those who moved to the US. As I will show in section 6, there was strong regional and family path dependence in destination choices, implying that migrants with the same surname tended to go to the same destination country. Yet, Figure 4 shows that there is still some overlap between the surnames of Italians going to Argentina and of those going to the US. In these figure, each dot represents a different surname. The y-axis represents the frequency of a given surname in the Argentine data and the x-axis represents such frequency in the US data.

The results using surname fixed effects (column 5) also indicate a higher likelihood of home ownership and a lower likelihood of being employed in an unskilled occupation for Italians in Argentina. This pattern is confirmed in column 6, where I estimate a regression including surname fixed effects but not including port of origin effects.[20] Note that, conditional on surname fixed effects, ports of origin do not add much predictive power to the regression, as indicated by the very similar R-squared in columns 5 and 6 of both panels.

One limitation of this exercise is that individuals with common surnames are unlikely to be related to each other. Hence, in Figure 5 I re-estimate equation 1 including surname fixed effects, while progressively excluding individuals with common surnames from the sample. To do so, I focus on surnames that show at least once in both the Argentine and US datasets, and then rank them in terms of their overall frequency. In the last row, I just include surnames that are in the bottom 10% in terms of frequency (which corresponds to surnames that show up at most 3 times in the combined Argentina-US linked samples). The results show a similar pattern than in the

---

[19]This strategy is used in Bleakley and Ferrie (2016). Olivetti and Paserman (2015) instead use the informational content of first names to measure social status.

[20]I estimate this model because the regional clustering of Italian surnames implies that, conditional on a surname, there is little variation in ports of origin.

baseline exercise.

4.4 Robustness to linking

One concern with the results is that incorrect links will result in pre-migration characteristics being measured with substantial error. To address this possibility, in Figure 6 I progressively exclude relatively lower quality matches from the Argentina and US samples. In the second to last row of the figure, I only include observations with a linking score above the 75th percentile of the distribution of linking scores within the Argentina and US samples. The figure shows a similar pattern regardless of the sample that I use.

Another concern is that the results might be driven by selection into the linked samples. First, note that the results in the cross section (which do not rely upon linking) are very consistent with the results that use the linked data. Yet, to further alleviate this concern, in the last row of Figure 6 I reweight the data to account for selection into the linked sample based on observable characteristics upon arrival.[21] The results are similar to those in the baseline sample, suggesting that selection into the linked samples (at least with respect to observable characteristics) is not driving the results.

4.5 Second-generation Italians in Argentina and the US

First-generation Italians in Argentina outperformed those who moved to the US. How persistent was this advantage? To answer this question, I estimate a version of equations 1 and 2 focusing on second-generation Italian immigrants.

A challenge in estimating this equation is that the 1895 Argentine census did not include information on parental place of birth. To obtain this information, I link males from the 1895 census to their childhood household in 1869, where they can be observed living with their parents. As a result, the sample is restricted to native-born males who were 26 to 44 years old in the 1895 census. That is, those who were old enough to be born by 1869, but young enough to still be in their parent's household by that year. Using these data, I am able to distinguish those with Italian parents from those with native-born parents. Further details on the construction of this sample are

---

[21]To estimate the weights, I use the estimates from tables A1 and A2 to predict the likelihood of a match for each individual. I then use the inverse of that estimated probability as the weight.

provided in Pérez (2017).

For the US, it is possible to identify the children of Italian immigrants without linking individuals across censuses, as the 1900 census included a question on parental place of birth. To improve the comparability with the Argentine data, I focus on US-born individuals who were at least 26 and at most 44 years old in 1900. Both in the Argentine and US cases, I define the sample based on the place of birth of the father.

Table 5 shows that the advantage of Italians in Argentina persisted into the second generation. Similar to the results in Table 1, columns 1 and 3 show the differences between children of Italian immigrants in Argentina and the US, whereas columns 2 and 4 look at this same difference but relative to the children of natives in each of the countries. The advantage of second-generation Italians in Argentina with respect to home ownership is close to that in the first generation. In contrast, there is a smaller gap in the likelihood of holding unskilled occupations, suggesting some convergence at least in this dimension.

There are two limitations of this exercise. First, second-generation Italians in this sample are not the children of Italian migrants in linked passenger lists to census data: To enter the passenger lists sample, a migrant had to arrive to the Americas by 1882 or later, but to enter the second-generation sample a person had to be in Argentina by 1869 or in the US by 1874. Second, because there was little Italian migration to the US before 1880, there are not many children of Italians in the US that satisfy this condition. Moreover, the Italians who had migrated to the US by 1874 might have represented a relatively selected group of "pioneer" migrants.

5   Mechanisms

The analysis above suggests a limited role for pre-migration characteristics in explaining the differences in economic outcomes between Italians in Argentina and the US. Why were Italians in Argentina relatively more successful?

5.1 Return migration

Research in history argues that differences in the "expected length of stay" of Italians in Argentina and the US might explain the different pattern of assimilation across the two countries.[22] Specifically, the argument is that Italians who migrated to Argentina (perhaps because of its closer cultural proximity with Italy) did so with a higher expectation of staying permanently, thereby having stronger incentives to invest in host-country specific capital.

There are four reasons why this mechanism is unlikely to fully explain the results. First, rates of return migration were actually similar in Argentina and the US for migrants in these arrival cohorts. Combining data on population stocks, arrivals and mortality (following the approach in Bandiera et al. (2013)), I estimate the rate of return migration for the cohorts who entered the Americas in the last three decades of the 19th-century to be about 30% for Argentina and 37% for the US.[23] Second, as shown in section 4.2, gender ratios and the fraction of children upon arrival were remarkably close for both groups, indicating a similar predominance of family migration in both flows (at least for these cohorts). Third, there were differences between both groups also by the second generation, which is inconsistent with the differences being driven just by a shorter-term orientation of Italians moving to the US. Fourth, the results are similar when restricting the sample to Italians who had spent at least 5 years in the Americas (Table B6 in the online appendix).

5.2 Competition from natives and other immigrant groups

Italians in the US likely faced more competition from other previously established immigrant groups than Italians in Argentina. By 1870, there were only about 17,000 Italians in the US, compared to more than 2.5 million migrants from the British Isles and 1.7 million migrants from Germany (Gibson and Jung, 1999). In 1869 Argentina, the 70,000 Italians were the largest immigrant group and constituted 40% of all the European migrants in the country. As a result, Italians who arrived to Argentina likely benefitted from a denser and more established network. In contrast, newly arrived Italians to the US might have only been able to obtain "those jobs scorned by the native

---

[22]For instance, (Baily, 1983, p. 295) states that "Those who migrated to Buenos Aires included [..] more people who intended to stay."

[23]To perform this calculation, I use the fact that $Emigrants_t = Immigrant\,Stock_{t-1} - Immigrant\,Stock_t + Arrivals_t - Mortality_t$. The information on population stocks is from the censuses. The information on arrivals to both countries is from Ferenczi (1929) and the information on mortality rates is from Somoza (1973).

born and the second-generation children of immigrants" (Klein, 1983, p. 318).

Moreover, Italians in the US tended to settle in the older regions of the US, and predominantly in cities. By 1900, 72% of Italians lived in the Northeast region and 75% lived in urban areas. Klein (1983) argues that the concentration of Italians in Northeastern cities hampered their prospects for long-term social mobility, as upward mobility in the US tended to be higher in younger and smaller places. This argument is consistent with recent quantitative evidence on historical differences in mobility across US regions. For instance, Feigenbaum (2017) shows that there was higher mobility in rural areas than in cities in the early 20th century. Similarly, Pérez (2019) finds higher rates of mobility in the Midwest than in the Northeast in the mid 19th century.

There are, however, two caveats to the plausibility of this argument. First, standard models of the labor market impacts of immigration predict that the labor market outcomes of Italian migrants should have actually been *hurt* by a larger Italian population at the destination. Moreover, in this case, the size of the Italian flow to Argentina was much larger than the flow to the US when considered relative to the size of the native-born population. Second, several studies (for instance, Beine et al. (2011) and Spitzer and Zimran (2018)) show that a larger immigrant stock at the destination is usually associated with a more negatively selected migration flow.

One way to offer some evidence on this issue is to analyze the extent to which Italians were relatively more successful in more recently settled places within the US. To do so, I estimate versions of equations 1 and 2 in which I split the US into four regions (Northeast, Midwest, South and West) and estimate a separate interaction term for each of them. Table B7 shows that there was a similar gap across US regions relative to Argentina in the likelihood that Italians would be employed in an unskilled occupation, ranging from 32 percentage points in the Northeast to 22 percentage points in the South. The results are similar regardless of whether I include natives or not in the sample.

Italians in the US Midwest and West had a higher likelihood of home ownership than Italians in Argentina. However, this advantage disappears when adding natives to the regression. Relative to the native born, Italians in all US regions were less likely to own property than Italians in Argentina. The smallest gap corresponds to the comparison between Argentina and the US West, while all the remaining gaps are of similar size.

In addition to competition from other immigrant groups, Italians in Argentina and the US also faced labor market competition from natives. While Italians in Argentina and the US had similar

levels of human capital upon arrival (at least as captured by their occupational structure, literacy and numeracy levels), Italians in Argentina had higher levels of human capital *relative* to the native born. For instance, among native males aged 18 to 60 years old, 89% of were literate in 1900 US but only 54% were literate in 1895 Argentina.

I next test whether the advantage of Italians in Argentina was driven by their higher human capital relative to natives. To do so, I estimate a version of equation 2 comparing Italians to natives in Argentina and the US in which I add literacy as a control variable. Adding this variable reduces the gap in the likelihood of home ownership by 5 percentage points and the gap in the likelihood of holding an unskilled occupation by 10 percentage points. Hence, these results suggest a quantitatively important role for differences in relative human capital in accounting for the advantage of Italians in Argentina. However, the remaining differences between the outcomes of Italians in Argentina and the US are still large in size.

5.3 Linguistic distance

The next hypothesis is that the closer linguistic distance between Italian and Spanish enabled Italians to sort into a broader range of occupations in Argentina than in the US. The main implication of this hypothesis is that Italians in Argentina must have had an advantage in accessing communication-intensive occupations compared to Italians who moved to the US (Peri and Sparber, 2009). To test this hypothesis, I classify occupations into "manual" and "non-manual" using the information from HISCLASS. I then estimate versions of equations 1 and 2 with an indicator that takes a value of 1 if the individual held a "manual" job as the dependent variable.

Panel (a) of Table 6 shows evidence consistent with this hypothesis. Italians in the US were overrepresented among those employed in manual occupations, both when compared to Italians in Argentina and when including the native born in the sample (so as to absorb differences in the relative availability of manual jobs in both economies).

The US census contains a question on English proficiency, which allows me to further investigate the relationship between language proficiency and occupational attainment. In the US, Italians were less likely to speak English than the average immigrant: About 60% of Italian males aged 18 to 60 spoke English in 1900, compared to 86% among the remaining immigrant groups. How important were these language barriers in preventing Italians from accessing non-manual occupations in the

US? To investigate this issue, I use the 1900 US census to estimate:

$$Manual_{ic} = \alpha_c + \beta_1 Speaks\,English_{ic} + \epsilon_{ic} \tag{4}$$

where $Manual_{ic}$ takes a value of 1 if migrant i from sending country c was employed in a manual occupation in 1900 US, α_c are country of origin fixed effects and $Speaks\,English_{ic}$ takes a value of 1 if the migrant reported being able to speak English.[24]

Panel (b) of Table 6 shows that there is an association between English proficiency and the likelihood of being employed in a manual occupation. In column 1, I just include Italians in the sample, whereas in column 2 I include all immigrant groups and net out country of origin fixed effects. Speaking English reduces the likelihood of being employed in a manual occupation by about 8.5 percentage points, relative to a baseline of 90%. This coefficient probably overestimates the true causal effect of English ability on occupational attainment, since this ability is likely positively correlated with other unobserved dimensions of human capital. Yet, the coefficients are similar in size to those in Ward (2018), who uses within-worker variation to estimate the effects of English ability on labor market outcomes during the age of mass migration.

A back of the envelope calculation based on these results suggests that language ability per se cannot fully explain the overrepresentation of Italians in manual occupations in the US relative to Argentina. Taking the above estimates at face value, if all Italians had been proficient in English, their proportion in manual occupations in the US would have decreased from 90 to 88%. In Argentina, however, just 80% of Italians were employed in a manual occupation. Hence, this calculations suggests that up to 20% ($\dfrac{90-88}{10}$) of the overrepresentation of Italians in manual occupations in the US can be accounted by their lower language ability.

The results on the second generation also suggest that linguistic distance per se cannot fully explain the disadvantage of Italians in the US: In 1900 US, more than 90% of US-born males aged 26 to 44 with an Italian father spoke English. Yet, the results in section 4.5 show that this group was also at a disadvantage relative to second-generation Italians in Argentina. Overall, while there is evidence in favor of this hypothesis, it seems unlikely to be the only explanation for the observed outcomes of Italians in the Americas.

---

[24]Specifically, the 1900 Census asked "Can the person speak English?".

5.4 Prejudice against Italians

A final hypothesis is that Italians in the US suffered more nativist prejudice and discrimination than Italians in Argentina. While it is hard to empirically prove such hypothesis, it is certainly consistent with the existing qualitative evidence. First, it is clear that Italians were culturally closer to the native born in Argentina than in the US: Argentina and Italy are both predominantly Catholic countries, that speak a Romance language and share a common Latin culture. In addition, the elites that governed Argentina during this period had a very positive of European immigration, which they considered a source of "civilization" for the country.[25]

In the US, in contrast, Italians and other "new immigrants" were the focus of renewed anti-immigrant sentiments by the turn of the 20th century. Indeed, the 1921 and 1924 quota acts were written with the explicit goal of reducing the number of these migrants, among which Italians were the largest national group (Goldin, 1994). Nativist prejudice against Italians was also associated with anti-Catholicism (Higham, 2002).

The reports of the Immigration Commission, a bipartisan Congressional Commission devoted to the study of European mass migrations to the US, contain several instances of discriminatory remarks against Italians, particularly southerners.[26] For instance, the reports argue that northern Italians would be more desirable immigrants because they "..are more easily assimilated than their southern countrymen, who, because of their ignorance, low standards of living, and the supposedly great criminal tendencies among them are regarded by many as racially undesirable" (Dillingham, 1911, p. 177). As this quote makes it clear, Italians were also portrayed as having high rates of criminality: the reports even warn about the mass emigration of Italian criminals to the US.[27] Overall, the Commission describes Italians as less desirable for the US than other immigrant

---

[25]For instance, Article 25 of the 1853 Constitution of Argentina stated that "The Federal Government shall encourage European immigration, and it may not restrict, limit, or burden with any tax whatsoever the entry into Argentine territory of foreigners whose purpose is tilling the soil, improving industries, and introducing and teaching the sciences and the arts."

[26]Southern Italians were considered to be of a different "race" than northern Italians in the writings of the Commission. "The Bureau of Immigration, following the general practice of ethnologists, divides the people of Italy into two races North Italians and South Italians" (Dillingham, 1911, p. 141). Southern Italians were not considered completely white by Anglo-Saxon standards. "Sardinians have a considerable infusion of Spanish blood, while the Neopolitans are said to incline slightly toward the African or negro type." (Dillingham, 1911, p. 177)

[27]"It is certain that many Italian criminals, both those who had served sentences and others who had escaped punishment, have come to the United States during the past 30 years. It was frequently stated to members of the Commission in southern Italy and Sicily that crime had greatly diminished in many communities because most of the criminals had gone to America." (Dillingham, 1911, p. 209)

groups.[28]

Italians in the US were even the subject of nativist violence, particularly in the US South. In the 1890s, more than 20 Italians were lynched in the US (LaGumina, 1999). The worst episode of violence took place in New Orleans in 1891, where a mob killed 11 Italians after a jury found them to be innocent of a killing. Another famous example is the 1927 execution of two Italian immigrants, Sacco and Vanzetti, who were accused of robbery and murder. This execution resulted in international protests due to the perceived bias of the judge and the prosecution.

This evidence can be complemented with historical survey data collected with the aim of measuring the prejudice of Americans against various nationalities and races. Bogardus (1928) conducted a survey in which 1725 (predominantly white) American college students were asked to express their preferences over 40 different races and nationalities.[29] The survey asked students several questions, including whether they would be willing to accept someone from a given group as a marriage partner, as a friend, or as a neighbor. Figure B2 shows that Italians fared similarly to other Southern Europeans in terms of the students' preferences, but consistently below Northern Europeans. For example, only 15.4% of the students declared to be willing to marry an Italian, 25% to be willing to accept an Italian as member of one's social club, and 35% to be willing to accept an Italian as a neighbor. The comparable figures for Germans are 54, 67 and 78.7%, and for Scottish are 78.1, 89.1 and 91.3%, respectively. It is worth noting that while Southern Europeans were ranked consistently below Northern Europeans, they were still ranked above groups such as African Americans, Asians and Mexicans.[30]

6 Understanding destination choices

Italian migrants and their children had higher rates of home ownership and were less likely to be employed in unskilled occupations when they migrated to Argentina. Why did (in an era of open borders) some Italians choose a destination that offered them limited prospects for upward

---

[28] "Treating an Italian from that standpoint, you will find the Italian as good as any of the other races from farther north, with the possible exception of those from Scandinavia and the British Isles." (Dillingham, 1911, p. 181). "As to the comparative value of the German and Italian emigrants to the south, I would say that the German has desirable qualities which the Italian has not. That is, the German is very solid; very solid; he does not get angry quickly." (Dillingham, 1911, p. 182)

[29] These data was recently used by Hilger (2016).

[30] For instance, the proportion of students willing to marry an African American, a Chinese, or a Mexican were 1.4, 1.1 and 2.8%, respectively.

mobility?

One potential explanation is that migrants deciding between Argentina and the US faced a trade-off between higher wages in the short term (when they moved to the US) and higher chances of upward mobility in the long run (when they moved to Argentina). Hence, for migrants who only wished to stay temporarily, migration to the US constituted a more attractive option due to its higher wages for unskilled jobs.[31] However, as discussed above, rates of return migration were actually similar in both destination countries, and the differences between Italians in Argentina and the US were also present by the second generation. Moreover, if the only reason why some immigrants chose Argentina is that the country offered longer-run payoffs than the US, Italians who moved to Argentina should have been on average younger than those who went to the US. Yet, the age structure upon arrival was very similar for both groups, Overall, it seems unlikely that the differences in outcomes were just driven by a shorter-term orientation of Italians who moved to the US.[32]

Another potential explanation is that immigrant networks (by reducing costs and mitigating the risks associated with migration) generated path dependence in destination choices within the Americas. In other words, for Italians deciding where to migrate, having relatives or friends in one of the destinations might have been the primary consideration.[33] Indeed, a number of scholars point to path dependence as the key driver of Italian migrants' destination choices within the Americas. For instance, Moretti (1999) writes that "In other words, neither wage differentials nor the probability of employment nor transportation costs can explain the choice of the destination country."[34] Moreover, the US Immigration Commission reported that more than 90% of Italians

---

[31]Williamson (1995) compares average real wages of unskilled workers across a number of countries, including Argentina and the US. By 1900, the ratio between US and Argentine wages was 1.27. Note that this ratio does not take into account that the gap between average wages and wages received by Italian workers might have been different in Argentina and the US.

[32]Another potential explanation is that the cost of the passage to the US was lower than the cost to Argentina, which resulted in Argentina attracting more positively selected migrants and more migrants with the intention of staying. However, while the trip from Genoa or Naples to Buenos Aires was about twice as long than the trip to New York, there were no large differences in the monetary costs of going to each of these destinations. Baily (2004) reports that, in 1902, the average cost of the trip was 173.8 lire from Genoa or Naples to New York and 174.6 lire to Buenos Aires. According to Baily (2004), "the cost of passage was of marginal significance in the choice between the two destinations."

[33]Arroyo Abad and Sánschez-Alonso (2015) show that ethnic networks were an important consideration in the occupational choices of Italians in late 19th century Buenos Aires.

[34]Hatton and Williamson (1998) shows that the stock of emigrants from a given Italian province across different destination countries had a strong association with subsequent province-level migration flows. A similar argument is made by Gould (1980), who describes the process of spatial diffusion through which emigration spread across Italian regions.Spitzer (2013) studies spatial diffusion in the context of Jewish emigration from Russia.

who entered the US were joining either friends or relatives (Baily, 2004).

I next use the passenger lists data to test whether Italian migrants were more likely to migrate to the destination to which their "friends and relatives" had migrated in the past. Because I do not directly observe family or friendship relationships among immigrants, I use the surnames of previous migrants to Argentina and the US to compute a proxy measure of the strength of a migrant's network at each potential destination. Specifically, for each immigrant i with surname s arriving at time t, I compute the "Argentina Surname Index" (ASI) as:

$$ASI_{ist} = \frac{\dfrac{\#Italians\,with\,surname\ s\,in\,Argentina}{\#Italians\,in\,Argentina}}{\dfrac{\#Italians\,with\,surname\ s\,in\,Argentina}{\#Italians\,in\,Argentina} + \dfrac{\#Italians\,with\,surname\ s\,in\,US}{\#Italians\,in\,US}} \qquad (5)$$

where the number of Italians in each of the sending countries is computed based on the number of arrivals up to year $t-1$.

This measure is based on Fryer Jr and Levitt (2004) and has been more recently used in economic history by Abramitzky et al. (2016).[35] It takes a value of 1 if the immigrant has a surname that, up to year $t-1$, can only be found among arrivals to Argentina, and takes a value of 0 if the migrant has a surname that can only be found among arrivals to the US. A value of 0.5 indicates a surname that is not indicative (among past immigrants) of a preference for Argentina or the US.[36] Because ASI_{ist} is undefined for immigrants whose surnames show up for the first time at time t, in the main analysis I assign a value of 0.5 to these surnames (reflecting that they are "neutral" surnames). However, the results are similar if I instead drop these observations from the sample.

Note that this index is an imperfect proxy of the relative network strength of a migrant. For instance, it does not capture connections to friends or to relatives with a different surname. In addition, it introduces noise because some individuals that share a surname might not know each other (although due to the regional clustering of Italian surnames, ASI will also capture past migrations of individuals with similar regional origins).

Figure 7 shows the average value of ASI, computed separately for immigrants in the Argentine

---

[35]Connor (2018) and Wegge (1998) also use surnames to measure immigrant's networks in historical data. My measure is close in spirit to that in Connor (2018).

[36]For Argentina, the stock of Italian surnames in 1882 is constructed using data on Italian surnames in the 1869 census of population. For the US, I measure the stock up to year 1882 using the surnames of immigrants arriving from 1855 to 1881 using the passenger lists data.

and US passenger lists, and by year of arrival. The figure clearly shows that Italians arriving to Argentina had surnames that were distinctively associated to previous Italian migrants to Argentina. To formally test for the role of relative network strength in explaining migration choices, I estimate the following model:

$$Argentina_{ist} = \alpha_t + \beta\,ASI_{ist} + \gamma X_i + \epsilon_{ist} \tag{6}$$

where $Argentina_{ist}$ is an indicator that takes a value of 1 if the observation belongs to the Argentine passenger lists, α_t represent arrival year fixed effects and X_i is a vector of individual-level characteristics. The coefficient of interest is β, which measures the association between migration decisions and the relative network strength of a migrant at each of the destinations (as captured by ASI). I emphasize that β does not necessarily captures a causal relationship, as there might be persistent characteristics that attracted immigrants to certain destinations within the Americas and which were also correlated with surnames, a common issue when measuring network effects using observational data (Manski, 1993).

Table 7 shows that ASI_{ist} is a strong predictor of whether an individual moved to Argentina or the US. Going from a distinctively "Argentine" to a distinctively "American" surname increases the probability of moving to Argentina by almost 50 percentage points. Column 2 shows that the results are very similar when I control for a vector of individual-level characteristics: gender, age, and the occupational category declared upon arrival. Indeed, there is little increase in the predictive power of the regression from adding these variables, which is unsurprising given the limited amount of selection on observables documented above.[37]

Table 7 also shows some heterogeneous effects consistent with a path dependence interpretation of the results. Columns 3 and 4 show that the association is stronger for women and for migrants who were less than 16 years old at the time of arrival. This pattern is consistent with adult males migrating first and then being followed by their families. The last column (where I focus on working-age males) shows that the association is stronger for those employed as either farmers or unskilled workers prior to migrating. This pattern is consistent with the migration decisions of

---

[37]This exercise raises a concern about the within-surname comparisons in section 4.3. Specifically, that individuals who moved to one of the destinations despite having a surname strongly associated with one of the destinations (that is, a value of ASI close to either zero or one) might have been selected in an idiosyncratic way. To address this concern, in Figure B3 in the Online Appendix I show that the results are similar when restricting the within-surname comparisons to individuals with relatively "neutral" surnames (that is, surnames which are not indicative of a preference for either Argentina or the US).

the unskilled being more sensitive to the presence of networks, perhaps due to liquidity constraints (McKenzie and Rapoport, 2007, 2010; Moraga, 2013; Wegge, 1998). Note, however, that in all cases the baseline effects are still large in size, suggesting that networks were important for migrants in general and not just for certain subgroups.[38]

7   Conclusions

During the age of mass migration, seven million Italians moved to either Argentina or the US. Prior work shows that Italians had faster assimilation in Argentina than in the US, but is inconclusive on whether this was due to differences in selection or to differences in host-country conditions. Using data linking Italian immigrants from passenger lists to censuses of population, I showed that differences in pre-migration characteristics cannot explain the relative economic success of Italians in Argentina.

Despite Argentina and the US both had open borders for European immigration and attracted Italians with comparable characteristics, their assimilation experiences were quite different in each of the countries. This finding raises doubts about the importance of immigration policy as a determinant of assimilation. Finally, the fact that Italians moved in large numbers to both countries despite these different assimilation experiences highlights the importance of path dependence in shaping migrants' destination choices.

[38]One concern with these results is that they might be driven by common misspellings of Italian surnames in the Argentine and US datasets. Table B8 in the online appendix shows that the results are nearly identical when computing ASI_{ist} based on a NYSIIS standardized version of the surname.

Figure 1: Number of yearly Italian arrivals to Argentina and the US
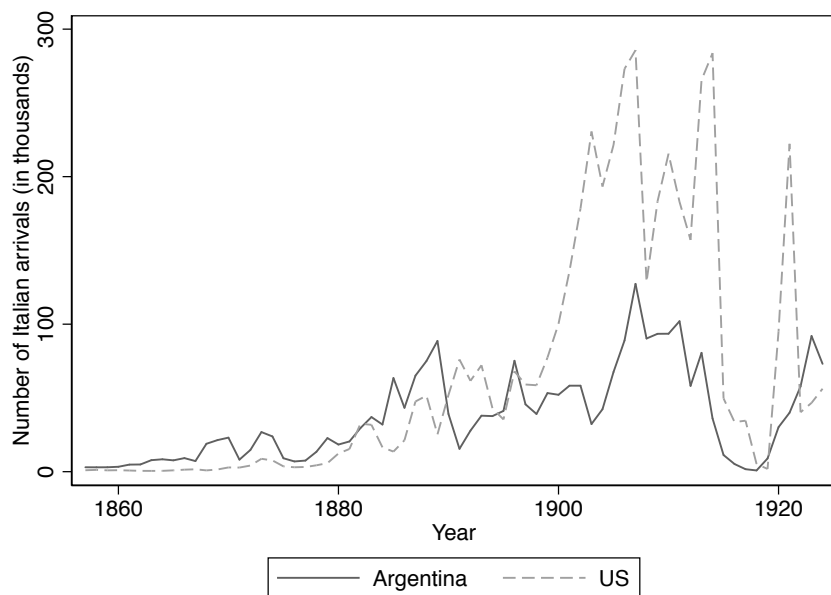

Notes: This figure shows the number of yearly Italian arrivals to Argentina and the US from 1857 to 1924.
Source: Ferenczi (1929).

Figure 2: Ports of departure of Italian migrants (1882-1900)

(a) Argentina

(b) US
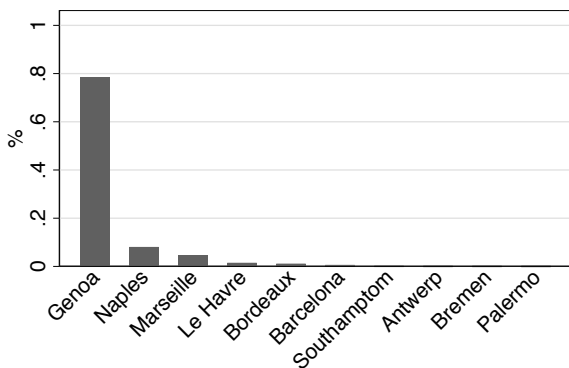

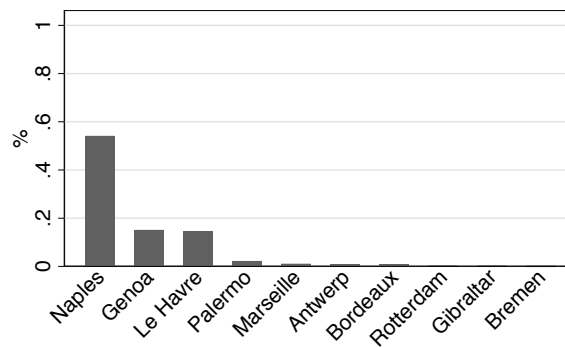

Notes: This figure shows the ten largest ports of departure among Italian immigrants to Argentina and the US.
Source: Passenger lists data as described in the main text.

Figure 3: Main economic outcomes, by years since migration

(a) Home ownership   **(b)** Unskilled occupation
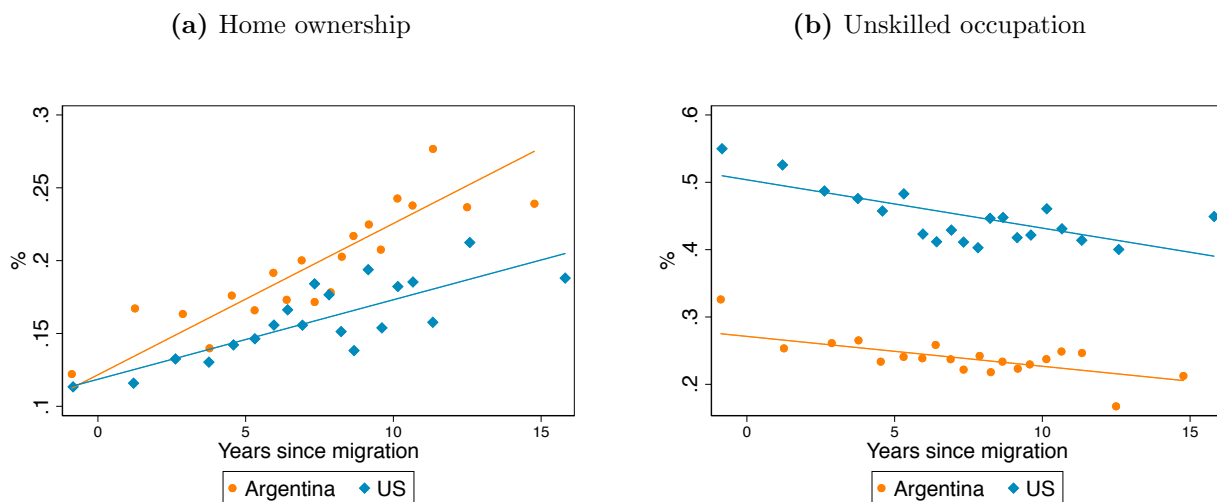

Notes: This figure shows a binned scatterplot of the main economic outcomes (y-axis) on years since migration (x-axis), net of age fixed effects, by country of destination.
Source: Data are from the samples linking passenger lists to the census as described in the main text.

Figure 4: Overlap between Italian surnames in Argentina and the US
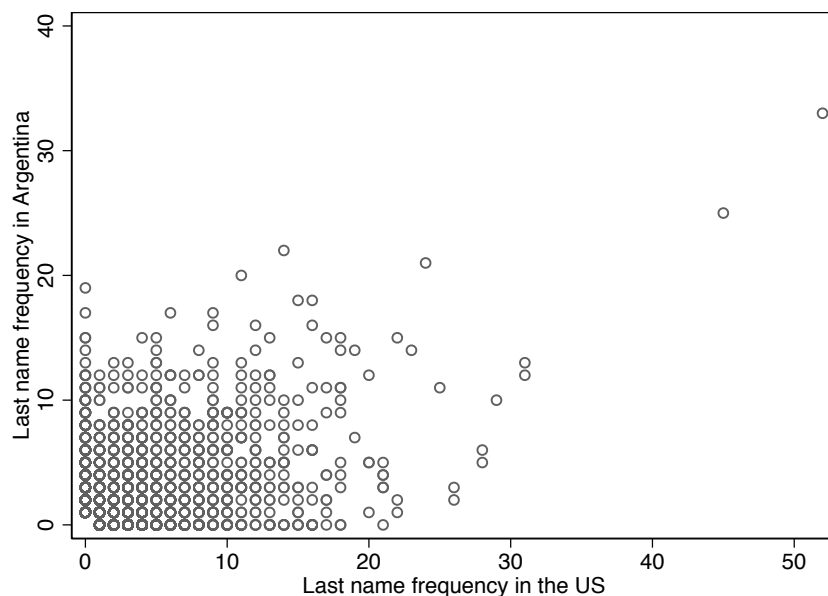

Notes: This figure shows the overlap between surnames of Italians arriving to Argentina and Italians arriving to the US. Each dot corresponds to a different surname.
Source: Data are from the samples linking passenger lists to the census as described in the main text.

Figure 5: Surname fixed effects, excluding common surnames

(a) Home ownership

(b) Unskilled occupation
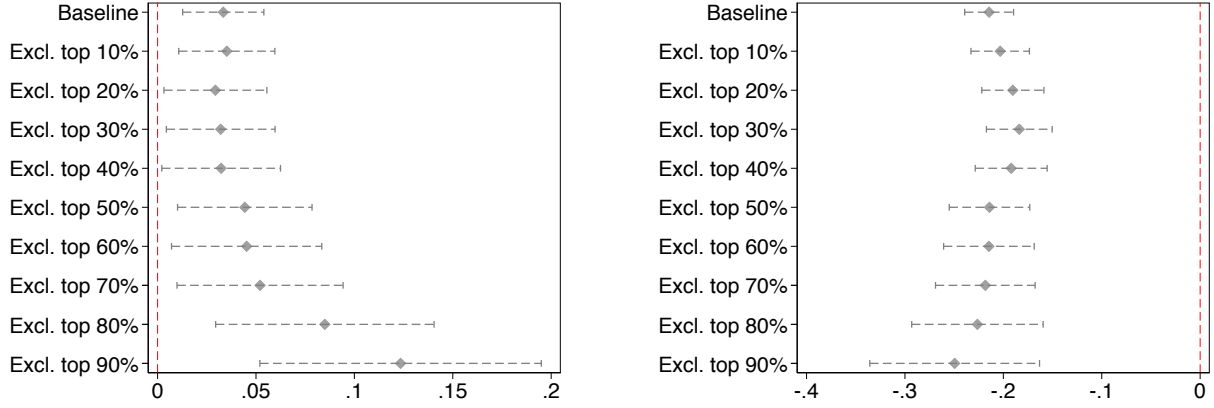

Notes: This figure shows the results of the specification using surname fixed effects after progressively excluding individuals with common surnames from the sample. In the last row, I just include those with a surname in the bottom 10% of frequency among those surnames that show up at least once in Argentine and US datasets. The specification corresponds to the one with the largest set of controls in Table 4 (including surname fixed effects). Source: Data are from the samples linking passenger lists to the census as described in the main text.

Figure 6: Robustness to linking procedure

(a) Home ownership

(b) Unskilled occupation
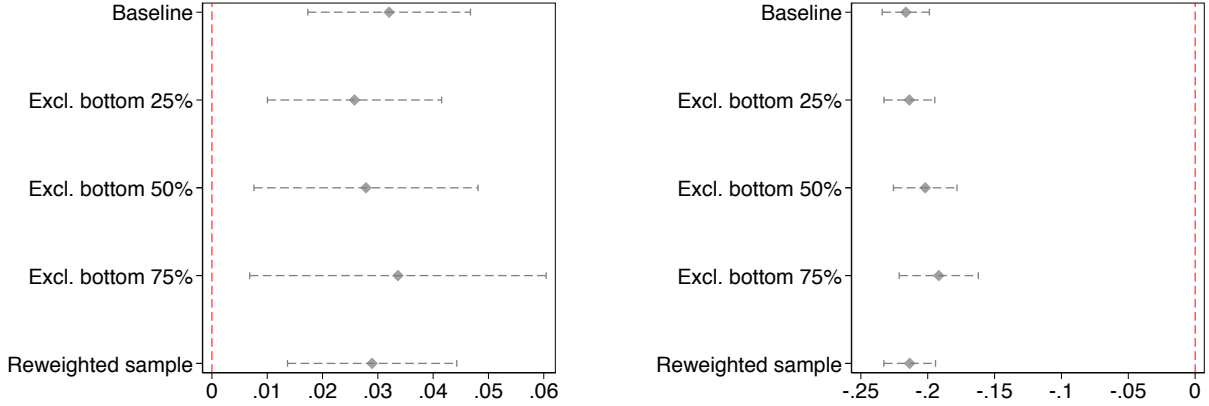

Notes: This figure shows the robustness of the results to progressively increasing the quality of the links and to selection into the linked samples. In rows 2 to 4, I progressively exclude observations with a linking score in the bottom 25, 50 and 75% within the Argentina and US samples. In the last row, I reweight the sample to account for selection into the linked sample based on observable characteristics. The weights are based on the probit estimates from tables A1 and A2.
Sources: Data are from the samples linking passenger lists to the census as described in the main text.

Figure 7: Argentine Surname Index, by destination country and year of arrival
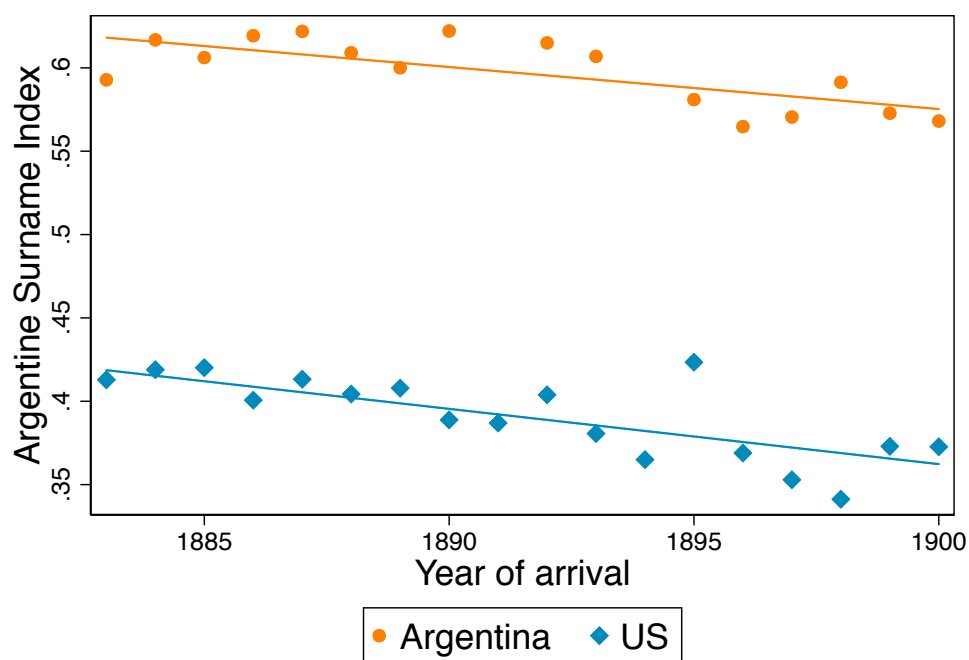

Notes: This figure shows the average value of the *Argentine Surname Index (ASI)* among arrivals to Argentina and the US. This index is computed based on the relative frequency of the surnames of all previous arrivals to Argentina and the US. A value of one indicates a surname that is only held by Italians who previously moved to Argentina, whereas a value of 0 indicates a surname that is only held by Italians who moved to the US.
Source: Passenger lists data as described in the main text.

Table 1: First-generation immigrants in Argentina and the US, cross-sectional data

	Home ownership		Unskilled occupation	
	(1)	(2)	(3)	(4)

Notes: $***p < 0.01$, $**p < 0.05$, $*p < 0.1$. This table compares Italians in Argentina and the US with respect to the likelihood of owning their home and the likelihood of being employed in an unskilled occupation. The mean of the dependent variable is computed among Italians in the United States. Column 1 just includes age fixed effects. Columns 2 to 6 include additional fixed effects as indicated by the table.
Sources: Data are from the samples linking passenger lists to the census as described in the main text.

Table 5: Second-generation Italians in Argentina and the US

					(0.00407)
Individual controls	No	Yes	Yes	Yes	Yes
Observations	1308843	1308843	1308843	1308843	778318
Mean of dep. var.	0.396	0.396	0.396	0.396	0.385
R^2	0.302	0.318	0.319	0.319	0.337

Notes: $***p < 0.01$, $**p < 0.05$, $*p < 0.1$. The dependent variable is an indicator that takes a value of 1 if the observation belongs to the Argentine data. The Argentine Surname Index (ASI) measures the relative frequency of an individual's surname in the Argentine and US data based on the surnames of previous Italian arrivals to Argentina and the US. The regressions with individual controls include indicators for age, gender, and occupational category upon arrival. The sample is restricted to arrivals from 1882 to 1900.
Source: Passenger lists data as described in the main text.

A   Data Appendix

A.1   Coverage of passenger lists data

Figure A1 compares the number of yearly arrivals as computed with the passenger lists data and according to Ferenczi (1929). In the US data, the number of Italian arrivals in the passenger lists closely tracks the figures in the official statistics. In the 1882-1900 period, there were 940,000 Italian arrivals according to Ferenczi (1929), and there are 820,000 records in the passenger lists data in this period.

The Argentine passenger lists data are less complete than the US data. There were 900,000 Italian arrivals to Argentina from 1882 to 1900 according to Ferenczi (1929), but there are 530,000 records in the passenger lists data. There are a number of reasons for this incomplete coverage. First, only migrants arriving through the port of Buenos Aires are included in the data (about 75% of arrivals). Second, the digitization effort prioritized those lists that were in the worst state of preservation. Third, some of the original lists were impossible to digitize due to their state of preservation. For instance, there are no data corresponding to the years 1891 and 1894 (a total of 87,000 records). Similarly, when collapsing the data at the year-month of entry, there are no observations for about 30% of the months.

One concern is the extent to which the digitized data for Argentina is representative of Italian arrivals in this period. Figure A2 compares the fraction of males among Italians in the passenger lists and the fraction of males among all immigrants (including non-Italians) according to Ferenczi (1929). The fraction in the passenger lists data tracks closely that in the official statistics. Similarly, Figure A3 shows that the age structure by arrival decade (1881-1890 and 1891-1900) of Italians in the passenger lists data and the age structure of all migrants according to Ferenczi (1929) are also close to each other.

Table A1: Which factors predict linking? Argentine data, probit marginal effects

	(1) 1 if in linked sample

Notes: $***p < 0.01$, $**p < 0.05$, $*p < 0.1$. This Table reports the probit marginal effects of a regression on the likelihood of being on the linked sample on observable characteristics upon arrival.
Sources: Cross-sectional data are from Ruggles et al. (1997).

Figure A1: Coverage of passenger lists data, Argentina and the US
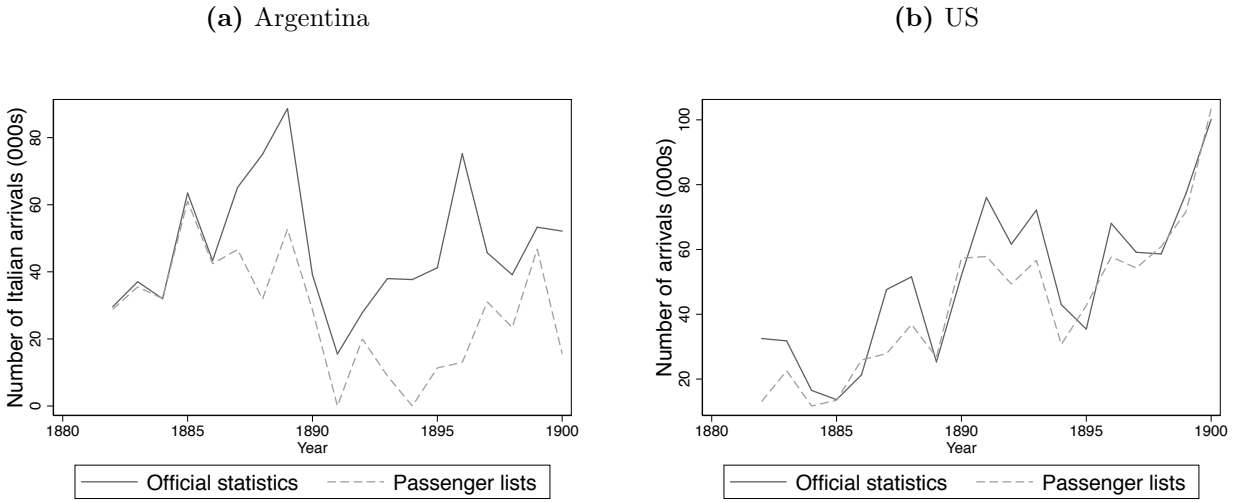

(a) Argentina   **(b)** US

Notes: This figure shows the annual number of Italian arrivals according to the passenger lists data and the overall gender ratio (including non-Italians) according to official immigration statistics for Argentina and the US based on the data in Ferenczi (1929).

Figure A2: Fraction of males among Italian arrivals to Argentina
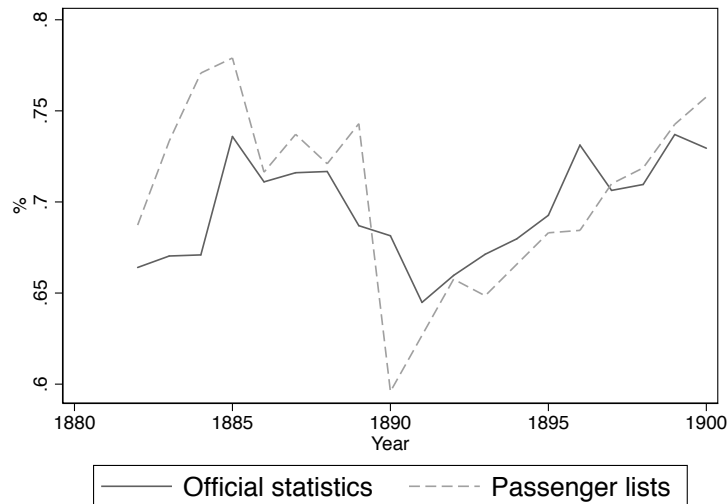

Notes: This figure shows the gender ratio of iItalian arrivals according to the passenger lists data and according to official immigration statistics for Argentina based on the data in Ferenczi (1929).

Figure A3: Age structure of Italians in Argentine data

(a) 1881-1890   **(b)** 1891-1900
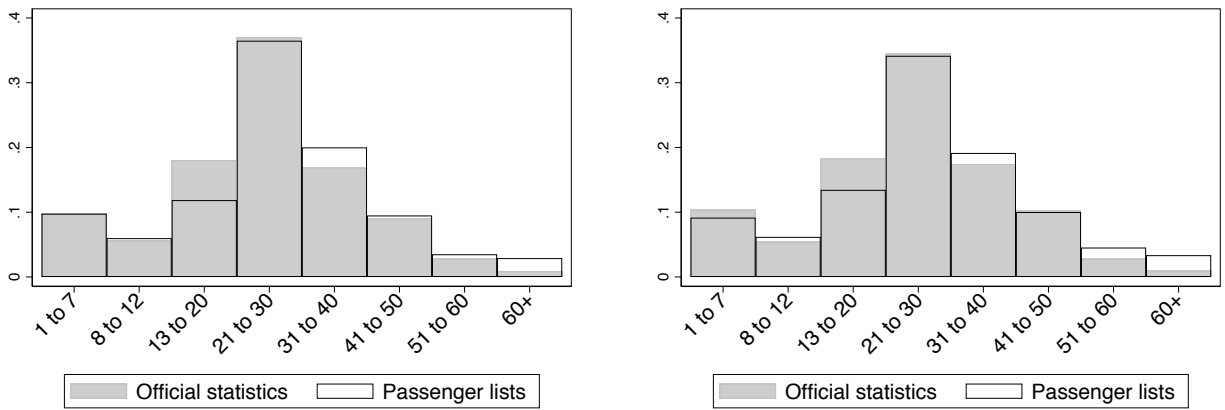

Notes: This figure shows the age structure of iItalian arrivals according to the passenger lists data and according to official immigration statistics for Argentina based on the data in Ferenczi (1929).

B   Additional Results

Figure B1: Age structure, Italian arrivals to Argentina and the US (1882-1900)
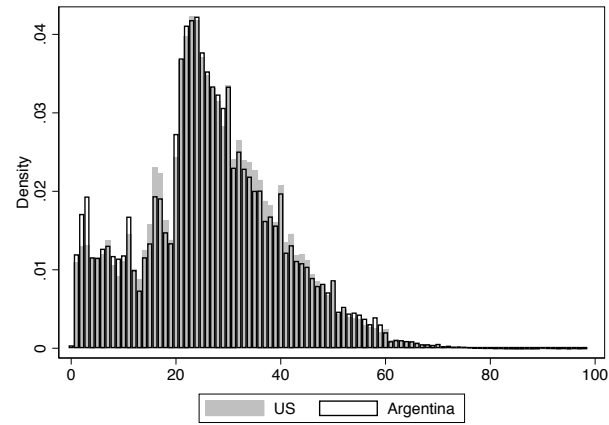

Notes: This figure plots the age distribution among Italian arrivals to Argentina and the US in the 1882-1900 period.
Source: Passenger lists data as described in the main text.

Figure B2: Prejudice against Italian Immigrants: % of respondents who would:

(a) Marry someone from this group
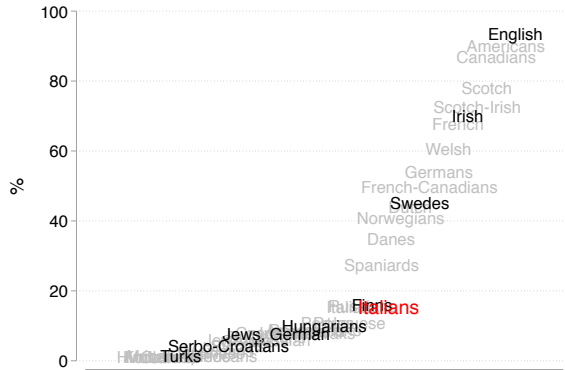

(b) Be friends with someone from this group
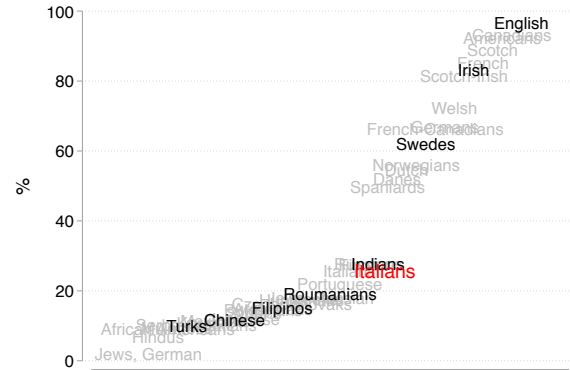

(c) Be neighbors with someone from this group

(d) Be in the same occupation
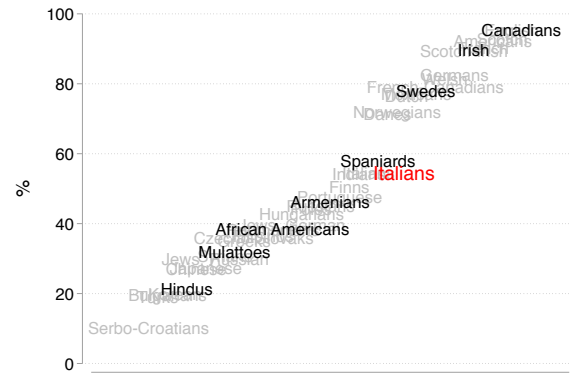

(e) Allow as citizen of my own country
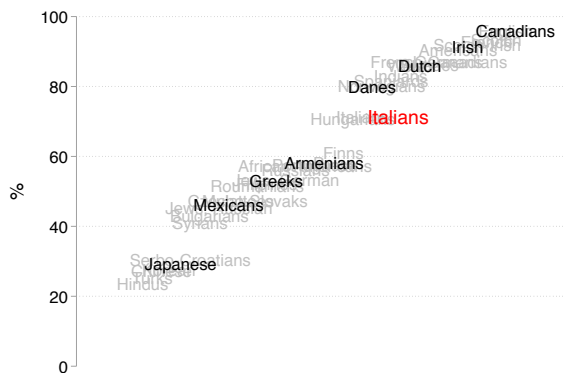

(f) Would only allow as visitors to my own country
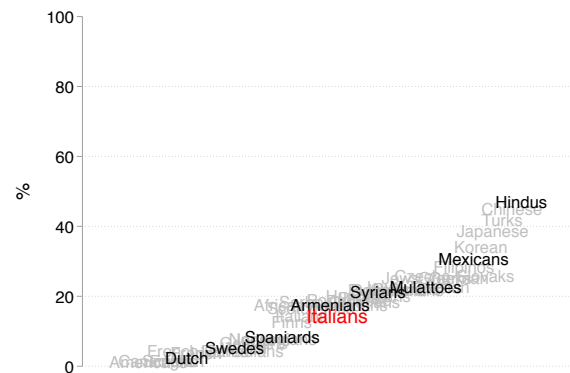

Notes: Each of the figures shows the percentage of individuals who reported being willing to accept someone from a given group as: (a) marriage partners, (b) friends, (c) neighbors, (d) workers in their same occupation, (e) citizens of their own country, and (f) only as visitors to their own country.

Source: Data are from a sample of 1725 American college students compiled by Bogardus (1928).

Figure B3: Surname fixed effects results using only "Neutral" surnames

(a) Home ownership   **(b)** Unskilled occupation
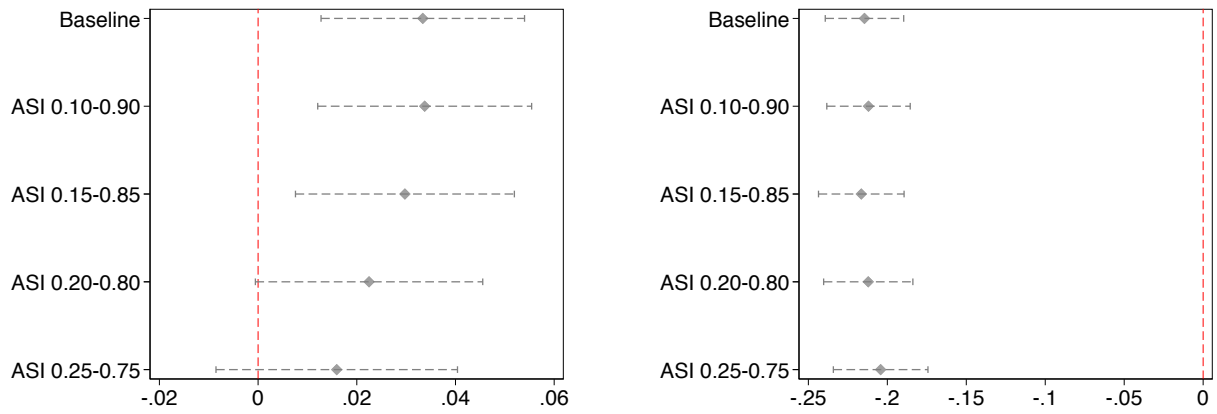

Notes: This figure shows the results after progressively excluding individuals with "distinctive" surnames from the sample (that is, surnames with values of the *ASI* either close to zero or close to one. The specification corresponds to the one with the largest set of controls in Table 4 (including surname fixed effects).

Sources: Data are from the samples linking passenger lists to the census as described in the main text.

Table B1: Occupational mobility from arrival and until the next census, southern Italians
