"Wait a Cotton Pickin' Minute!"
A New View of Slave Productivity

Alan L. Olmstead and Paul W. Rhode

June 2005

Alan L. Olmstead is Professor of Economics and Director of the Institute of Governmental Affairs at the University of California, Davis, and member of the Giannini Foundation of Agricultural Economics. Paul W. Rhode is Professor of Economics at the University of North Carolina, Chapel Hill, and Research Associate at the National Bureau of Economic Research.

A number of talented students have contributed to the collection and analysis of the data. Heading this list are Janine L. F. Wilson and Jeffery Graham who have served as the project’s head research assistants. Amir Amadi, Audrey Goodwater, Pablo Jenkins, and Teresa Nguyen at UC, Davis; Tiffany Hamelin at the University of Mississippi; and Peter Malaspina at the University of North Carolina have all spent countless hours mulling over plantation records. We give special thanks to Shelagh Mackay, whose attention to detail and insights have left a positive mark on our research. Librarians across the South have been of great assistance in identifying sources. We would like to single out Tara Z. Laver at Louisiana State University and Jennifer Ford at the University of Mississippi for their special efforts. Dale Flesher and Mary Jones have both graciously opened their private records to us. We have benefited from the comments, help, and interest of Lety Arroyo-Abad, Louis Cain, Lee Craig, Gregory Clark, Peter Coclanis, Stanley Engerman, Timothy Guinanne, Mary Jackman, John Hebron Moore, Joel Mokyr, Chiaki Moriguchi, Gavin Wright, as well as the seminar participants at the Department of Agricultural and Natural Resource Economics Workshop at UC Davis, the Economic History Workshops at Northwestern, Stanford, and Yale Universities, and the Alfred D. Chandler Lecture at the University of North Carolina, Chapel Hill.

This working paper is circulated to invite discussion and critical comments. Because it is work in progress, it should not be cited without the permission of the authors.
"Wait a Cotton Pickin' Minute!"
A New View of Slave Productivity

Abstract: Questions concerning slave efficiency have long fascinated economists and historians, and over the past 30 years few, if any, issues have been more contentious. Cliometricians have generally focused on cross sectional questions such as whether slave plantations were more efficient than free-labor farms in the North and South. In doing so, the cliometrics literature has ignored the findings of an older generation of economic historians who pointed to the importance of biological innovations in propelling the South’s growth. Resurrecting this older and more literary tradition, our primary interest is decidedly dynamic. Our scaffolding is built on the solid foundation of over 400 thousand daily cotton picking observations drawn from the archives of over 60 slave plantations. We show that in the 50 years preceding the Civil War the average amount of cotton picked per slave in a day increased by two and one-half times. This finding bears on a wide range of issues discussed in the cliometrics literature including the movements in slave, cotton, and land prices, the factors responsible for the growth of cotton output and the spread of cotton cultivation, the sources of the differences in regional production and productivity between the Old and New South, the movement of slaves out of urban employment into cotton production, as well as the traditional static comparisons of plantation and non-plantation efficiency.

After a lengthy absence, slavery is reclaiming a share of the spotlight in American economic history research. The “Peculiar Institution” is the subject of a number of recent works by leading economic historians including Robert Fogel’s *Slavery Debates*, Gavin Wright’s forthcoming Louisiana State University lectures, and several contributions to the festschrift honoring Stanley Engerman, *Factor Endowments, Labor and Economic Growth in the Americas*.¹ In addition, in an important series of papers, Engerman together with Ken Sokoloff have placed the prevalence of slavery and highly unequal wealth distribution at the center of their macro-level explanation for why some European colonies achieved modern economic growth early whereas others lagged. Much of this literature synthesizes and reinterprets existing evidence with the aim of providing perspective and even closure on long-standing debates. We pursue a different tack by bringing new data to the table. Drawing on an extensive dataset on slave cotton picking

---

rates, this paper takes a fresh look at changes in slave and plantation efficiency over the half century before the Great Emancipation.

Our work builds on a productivity story that has long been part of the broader economic history literature asserting that a succession of biological innovations significantly improved cotton yields, quality, and picking efficiency in the antebellum years. The innovations included the introduction, selection, and diffusion of new cotton varieties and a complex process of biological learning as planters adjusted their day-to-day practices and perfected varieties suitable to an ever wider range of cultivation. The mainstream economic history debate on slave and plantation efficiency has largely ignored this evidence, paying little attention to changes in cotton raising technologies during the antebellum years. While this literature has concentrated on cross sectional questions such as whether slave plantations were more efficient than free-labor farms in the North and South, our interest is decidedly more dynamic.

The story of the improvement of cotton varieties has great significance for understanding southern economic development. For a period when many have decried the lack of indigenous technological advances in the South, the region was the undisputed world leader in the creation and diffusion of new, superior cotton varieties. The achievements of antebellum southern breeders far surpassed anything accomplished by northern wheat breeders in the pre-Civil War era. Employing a sample of over 400,000 individual picking entries, we show that in the 50 years preceding the Civil War the average amount of cotton picked per slave in a day increased by two and one-half times. This finding bears on a wide range of issues discussed in the mainstream economics literature including the movements in slave, cotton, and land prices, the factors responsible for the growth of cotton output and the spread of cotton cultivation, the sources of the differences in regional production and productivity between the Old and New South, the movement of slaves out of urban employment into cotton production, as well as the traditional static comparisons of plantation and non-plantation efficiency. But, most importantly we direct attention to the hitherto neglected issue of the dynamic changes in slave productivity.
The Cliometric Mainstream

To cite all those who have participated in the debate on slave efficiency over the past thirty years would make for a very long footnote. Addressing the population of economic historians over 40 years of age, it might be easier to cite those who have not published on this subject. We are on that shorter list and thus are green hands in the field of slavery studies. The longer list of seasoned hands would include Fogel and Engerman for *Time on the Cross*, and Fogel and the many other contributors to the four volumes of *Without Consent or Contract*.² Gavin Wright, Peter Temin, Paul David, Roger Ransom and Richard Sutch, William Parker, Robert Gallman, Chris Hanes, Claudia Goldin, Lee Craig, Tom Weiss, Fred Bateman, James Foust, and well over a score of other prominent scholars have made substantive contributions. Parker and Gallman (along with their students) played a key role in shaping the contours of the debate by providing their much-cited sample of over 5,000 farms drawn from the 1859 manuscript census.

In *The Slavery Debates* (2003) Robert Fogel offered his view on the state of knowledge of slave and plantation efficiency. Notwithstanding all of the fireworks concerning *Time on the Cross*, Fogel concludes that its major findings remain intact. In particular, he maintains that slavery was a viable and robust labor system, and slave plantations were highly profitable, efficient, and fully capable of out-competing free farms. The greater efficiency of plantations stemmed from their ability to exploit the gang system. Slaves “who toiled in the gangs of the intermediate and large plantations were on average over 70 per cent more productive than either free farmers [northern and southern] or slaves on small plantations.” Finally, Fogel asserts that under the gang system slaves worked more intensely but for fewer hours than free workers. The greater intensity of labor per hour, rather than more hours of labor per day or more days

---
of labor per year, is the reason the index of total factor productivity is 39 percent higher for the gang-system plantations than for free farms.”

The mainstream literature on slave efficiency is for the most part static, focusing on cross-sectional comparisons in 1859. This is no doubt in large part due to the heavy lifting done by Gallman and Parker. As Wright has noted, the focus on a single crop year raises possibility that the results may be unrepresentative because 1859 was an exceptional year for cotton production and southern income and a relatively poor year for northern agriculture. (Relying on cross-section data also presents difficulties in controlling for unobserved differences or heterogeneity across farms/plantations that cause problems of endogeneity.)

Figure 1 plots the long run trends in cotton production (in logs) along with the real prices of both cotton and prime-age male slaves. The data depict a dynamic and expanding economy. Over the 1820-60 period, the quantity of cotton produced increased by almost 6.0 percent per annum whereas the real price of cotton fell by 0.8 percent per year and the real price of prime age male slaves rose by 1.8 percent. In *Time on the Cross*, Fogel and Engerman observed that productivity must have been rising: “The basic cause of this long-term decline [in cotton prices] was the steady increase in productivity. Among the developments which made cotton farming increasingly more efficient were the improvements in the varieties of cottonseeds, the introduction of the cotton gin, the reduction in transportation and other marketing costs, and the reallocation of cotton production in the more fertile lands of the New South.” But this passage is their only acknowledgement of the possible impact of new cotton varieties.

---

3 *Slavery Debates*, pp. 28-39. Fogel argues that small slaveholders (those with 1-15 slaves) could not effectively capture the benefits of the gang system, so plantations with more than 15 slaves account for nearly all of the productivity advantage. Large plantations were only slightly more efficient than intermediate size units. The gang system propelled slaves to work with “less wasted motion,” with an “unremitting, machine-like quality.” *Without Consent or Contract*, Vol. 1, p. 79. “It was the gang system that forced men to work at the pace of an assembly line (called the gang) that made slave laborers more efficient than free laborers.” *Without Consent or Contract*, Vol. 1, p. 79. The work schedule was the result of a conscious decision of slave owners. Long rest periods during the day and more time off on the weekend were not “boons that slaveholders granted to their chattel but ...conditions for achieving the desired level of intensity.” Fogel, *Slavery Debates*, p. 33; Fogel, *Without Consent or Contract*, Vol. 1, pp. 78-79.

4 The mainstream economics literature does use census data to discuss the changes in cotton output and southern income between 1840 and 1860.

In a 1977 article, Fogel and Engerman address the question: “What then explains the big increase in the output of cotton between 1850 and 1860?” They estimated that the westward shift in cotton production explained about 8 percent of the increase in output between 1850 and 1860, and that the increase in improved land within each state explained 41 percent of the growth in output. They then deduced that 42 percent of the increase in output resulted from a substitution of land within states from other crops to cotton. “These estimates leave a residual of 9 percent to be explained by all other factors including increases in the use of fertilizers, increases in the labor-to-land ratio, and

random fluctuations in yields.” The subsequent debate on the sources of the increase in cotton output carried on in this tradition by offering various refinements, but there is no hint that biological innovations may have played an important role.

A handful of cliometricians have recognized the significance of productivity growth, but their work hardly caused a ripple, let alone altered the flow of the mainstream literature. Franklee Whartenby made the most serious investigation of antebellum productivity growth. Her findings offer a quantitative estimation of what an older generation of economic historians had long been saying. Between 1800 and 1840, a period when annual southern cotton production increased from 40 to 871 million pounds, Whartenby estimates that yields per acre increased by 46 to 78 percent. Relying on the earlier literature, Whartenby also commented on the change in picking efficiency due to the introduction of new varieties. “With the advent of Petit Gulf cotton in the late 1820’s, the daily picking averages jumped from about fifty or sixty to about 125 to 150, with as much as 300 or more sometimes reported.”

Looking at all tasks, Whartenby’s lower

---

7 Franklee Gilbert Whartenby, *Land and Labor Productivity in United States Cotton Production, 1800-1840* (New York: Arno Press, 1977), pp. 54, 104-105. Many other factors in addition to a change in varieties were at play because the center of cotton production moved onto more fertile western lands, but production in some regions was moving from high yielding valleys to upland regions. Whartenby’s mentor, William Parker, also pondered changes in cotton picking efficiency in his quest to construct a decomposition of the changes in labor productivity in cotton farming (much like his estimates with Judith Klein for grains) between 1840-60 and 1900-20. Parker examined a large number of plantation records and developed estimates of the labor requirements for 10 major cotton growing activities, including breaking, bedding, planting, and the like, but he was stymied by the picking question and simply assumed that picking efficiency remained constant. In doing so he noted that this assumption still had to be checked and that he had located but not analyzed an abundant sample of picking times in plantation records. W. N. Parker, “Labor Productivity in Cotton Farming: The History of a Research,” *Agricultural History*, 53: 1 (January 1979), pp. 228-244, esp. p. 235. Jacob Metzer, “Rational Management, Modern Business Practices, and Economies of Scale in Antebellum Southern Plantations,” *Explorations in Economic History*, 12 (1975), pp. 123-50 did examine daily picking rates on the Leak plantation in Tippah, MS over the 1841-60 period in order to investigate the treatment of pregnant women.

8 Whartenby, *Land*, pp. 104-05. In the spirit of our work on wheat, these calculations do not fully capture the effects of biological innovations because they do not account for the strong likelihood that without the infusion of new varieties, yields would have declined significantly due to a changing disease, pest, and weed environment. In particular, the cotton worm evidently first appeared in 1804 and the spread of Johnson grass, which was introduced in 1840s, significantly increased the problem of weed control. In addition to maintenance problems, Whartenby’s estimates do not account for the difficulties growers would have faced pushing out the frontiers of the cotton belt without varieties tailored for the new geoclimatic
bound estimate is that output per worker in 1840 was about double that of 1800. She, however, regarded her sources as too limited to allow drawing firm conclusions.

Stanley Lebergott took the analysis of the change in picking rates a step further in his 1984 textbook. In his characteristic fashion, Lebergott pieced together fragmentary evidence from secondary sources to produce the enlightening data in Table 1.

Source and Notes: Stanley Lebergott, *The Americans: An Economic Record*, pp. 168, 176. The Cost Approach used by Lebergott compares the cost or piece rate for picking 100 pounds of seed cotton with the farm wage rate to determine the implicit amount picked.

The assembled data indicate that cotton picking rates increased from 50 pounds a day in 1800 to 200 pounds a day in 1860. The scattered nature of the sources, the dependence on retrospective estimates, and the prevalence of round numbers suggest these results are best not considered definitive. While the direction of the change is clear, its timing and magnitude are not.

with seven of his sample plantations in South Carolina and one in Florida.\(^{10}\) As the title of Campbell’s thesis indicates, he had a broad set of interest that dealt with gender and demography, but in the process of exploring these matters he clearly examined the affects of the new varieties on a number of issues central to our work, including the gender division of labor, changes in seasonal labor demand, and the organization of the harvest. Whartenby, Campbell, and Lebergott’s works serve as a natural bridge to our next section, in a sense a bridge between two cultures.

**Less Charted Waters**

The “broader economic history literature” that we alluded to in the introduction emphasizes the impact of biological innovations in the antebellum cotton industry. The most recent proponent is John Hebron Moore (1956, 1958, and 1988), who argued that a succession of new cotton varieties revolutionized American cotton production by increasing yields per acre, picking efficiency, and the average quality of upland cotton.\(^{11}\) Moore is only the most recent of a long line of prominent scholars who have espoused this view. Many of the essential ingredients of Moore’s argument are readily available in the classic accounts of James L. Watkins and Louis Cecil Gray.\(^{12}\) The cliometrics literature repeatedly cites Watkins and Gray on myriad issues, but not on the importance of biological innovation. In fact, the mainstream economics literature has never disputed

---

the claims that picking efficiency soared; it has simply ignored this evidence. It is important to the quality of the documentation underpinning the traditional accounts. Moore, Watkins, Gray, and others based their claims on a wide variety of independent contemporary sources and first hand accounts that include antebellum agricultural journals, newspaper articles, archival testimony, and B. C. L. Wailes’ well-known 1854 treatise on Mississippi agriculture and geology. All clearly and forcefully testified to the events in question.

De Bow’s (1852) commentary on the 1817 Cotton Book of G.W. Lovelace of Sicily Island, Louisiana offers a clear indication of the quality of the nineteenth century evidence attesting to how changes in cotton varieties affected picking efficiency, yields, and ease of ginning.

In the time we speak of, i.e., the few last years of the past century, and upwards, to about 1810, the black seed cotton was the only kind raised here, or, in fact, anywhere in our country. This was not so productive as the Tennessee green seed, which came into use about this latter date… The little green seed was harder to pick than the black seed, and also harder to gin on the roller, or saw gin either. We give here an extract from the Cotton Book of G.W. Lovelace for October, 1817 when he raised the green seed cotton. He was a good thrifty planter in his time, and had some choice negroes; and here now is a specimen of their day's pickings for one week:

On looking over the same book for the month of December, when the weather was colder, there is a proportional falling off in the picking.

De Bow’s further commented that by 1852 many slaves, who were of comparable quality to Lovelace’s hands, could pick as much in a day as pickers 35 years before could pick in a week. Thus the general outline of the argument we are advancing has a strong

13 B. C. L. Wailes, Report of the Agriculture and Geology of Mississippi Embracing a Sketch of the Social and Natural History of the State (Jackson, MS: E. Barksdale, State Printer, 1854). Wailes was a prominent antebellum Mississippi planter and the founding president of the Mississippi Historical Society. His account is based on personal observation and on the testimony of older planters.

quantitative pedigree and was widely accepted in the antebellum South. Before empirically investigating the antebellum growth in picking efficiency, it is important to gain a longer view of the history of the cotton plant in the American South. This perspective reveals cotton-producing technologies were never constant.

The Creation of American Upland Cotton Varieties

There is voluminous, albeit sometimes contradictory, information about the introduction of cotton varieties into what would become the United States. Cotton of the *Gossypium arboreum* species was purportedly grown in Jamestown as early as 1607.\(^{15}\) And the colonists who emigrated from Barbados to settle the Carolinas under the Lords Proprietors brought *G. barbadense* seed with them. The planters cultivated this variety, originally from Brazil, extensively in the 1690s before shifting to rice and indigo.\(^{16}\) In Georgia, botanists at the Trustees’ Gardens in Savannah, an early type of agricultural experiment station, grew several varieties of cotton from the 1730s on. During the colonial period, the search to find suitable cotton varieties became truly a global undertaking. Planters experimented with seeds imported from the West Indies, Mexico, Central America, Brazil, Peru, the Middle East, South East Asia, and China. Table 2 itemizes some of the major imports after 1700. Foreign introductions, once adapted to local conditions, provided the foundation stock for the American domestic varieties. The usual stylized rendition of the early development of the American upland cotton industry has several important elements. Changes in spinning technologies led to an increase in the demand for upland cotton. Try as planters might to expand production, supply did not keep pace with demand largely because of the cost of separating the cotton lint from its fuzzy seeds. Eli Whitney’s cotton gin broke this bottleneck making possible

\(^{15}\) See Angele Lakwete, *Inventing the Cotton Gin: Machine and Myth in Antebellum America* (Baltimore: Johns Hopkins Univ. Press, 2003) who notes pp. 22-23 that Richard Haklukt’s 1607 report claimed the colonists grew this Old World cotton species and that the Records of the Virginia Company included cotton eighth on a 1620 list of 54 commodities grown in the colony. Native peoples in the Southwest had grown *G. hirsutum* varieties for over one thousand years by the time of European contact.

the expansion of production and breathing new life into the slave system. When judged against the realities of the antebellum era, this picture is seriously out of focus.

Learning to improve the seeds was every bit as important as learning to remove them. In the words of J. O. Ware, one of the leading breeders and students of cotton in the early twentieth century, the varieties that became the basis for the South’s economic development were a local invention, a distinctive “Dixie product.” “Although the stocks of the species were brought from elsewhere, new types, through [a] series of adaptational changes, formed this distinctive group the final characteristics of which are a product of

---

17 Lakwete, *Inventing*, pp. 1-96 makes a strong case that the ginning bottleneck was not as server as generally thought.
the Cotton Belt of the United States.”\textsuperscript{18} Plant scientists John Poehlman and David Sleper observe that the cotton stocks initially introduced into the South were largely mixed populations with varying amounts of cross-pollination and heterozygosity that gave them plasticity and potential for genetic change. They were tropical in origin, perennial, photoperiod-sensitive, and did not flower under the long days of the United States Cotton Belt. Yet, following generations of repeated selection, these initial stocks were molded into early maturing, photoperiod-insensitive cultivars adapted for production in the southern United States Cotton Belt. \textsuperscript{19}

In its native environment in Central America, upland cotton, \textit{G. hirsutum}, was a frost-intolerant, perennial shrub with short-day photoperiod response. As a short day plant, its flowering was triggered when the nights began to grow longer and cooler in the late summer or autumn. This strategy was adapted to a semi-tropic, semi-arid environment where the rains came in the autumn. At higher latitudes of the American South, there is greater variation in day length over the seasons and the date with the right conditions to trigger flowering occurred later in the year. This delayed maturation in an environment where the first frost occurred earlier. (The wet summers of the American South also served to relax the moisture constraint on the flowering and fruiting processes.) Initial attempts to grow upland cotton in the areas that now constitute the United States faced severe difficulties. Success depended on finding a mutation/cross or introducing a variety with the appropriate photosensitivity characteristics.\textsuperscript{20} The varieties

\textsuperscript{18} J. O. Ware, “Origin, Rise and Development of American Upland Cotton Varieties and their Status at Present,” \textit{Mimeo}, University Of Arkansas College of Agriculture, Agricultural Experiment Station, Fayetteville, Arkansas, 1951, p. 1. Our treatment (as do the published works of a number of plant scientists) relies heavily on Ware, so a short note to his expertise is in order. Ware was one of the USDA’s most prominent plant breeders and agronomists. He published extensively on a number of issues related to cotton culture. This unpublished manuscript is probably the single best account of the origins and evolution of upland cotton.

\textsuperscript{19} John M. Poehlman and David A. Sleper, \textit{Breeding Field Crops}, 4\textsuperscript{th} Ed. (Ames, IA: Iowa State Univ. Press, 1995), p. 376. They note on p. 374 “The early history of American Upland cotton is complex due to the genetic diversity of the early cottons introduced into the southern states; the frequent occurrence of cross-pollination among the different types; and the rapid genetic adjustment in cotton to climatic differences and cultural practices in the southern states in comparison to the tropical climate and primitive cultural practices in the regions where the cottons originated. A major adjustment that had to be made was the adaptation to longer photoperiods. The adjustments were hastened by the contributions of large numbers of early cotton breeders who worked without the genetic guidelines available to cotton-breeders today.”

\textsuperscript{20} S. G. Stephens, a leading cotton expert, has suggested two paths for the development of day-neutral upland cotton. The first is a cross with of \textit{G. hirsutum} with a day-neutral \textit{G. barbadense} variety from the West Indies. The second is the importation from Guatamala or Mexico of the race \textit{latifolium} of \textit{G. hirsutum} (e.g. Acala), the only form of “day-neutral” upland cotton. S. G. Stephens, “Some Observations of Photoperiodism and the Development of Annual Forms of Domesticated Cottons,” \textit{Economic Botany} 30 (1975): 409-18. Stephens concluded p. 17: “Annual Upland cottons, grown in the southern United States
eventually prevailing in the United States typically flowered in early to mid-summer and began to reach maturity by the end of August or early September.

The process of molding upland cotton to the environment was repeated over and over again as new varieties were introduced and as cotton production moved into new areas. In Lebergott’s words it was a matter of “try and try again.” According to Ware, “The vast differences in climate and soil that obtain over the Cotton Belt undoubtedly brought about a kind of natural selection which eliminated many of the kinds that were tried, while others became adapted to the several conditions under which they were grown and selected over a period of years.” American upland cotton was relatively late to come onto the world market, but its characteristics made it “much more suitable, than any other kind, for general factory use.”

The most common upland variety in the Colonial period was Georgia Upland (aka Green Seed, Georgia Green Seed). Several accounts assert that Green Seed was first grown in North America in 1733/34 at the Trustee’s Garden of the Georgia colony. It is likely that this variety made its way to Georgia from the Isle of Guadeloupe via England. By later standards, Georgia Green Seed was a low quality, low yielding, low value, short staple variety that was hard to pick. As with most upland varieties its seeds were “fuzzy,” meaning that they adhered to the fiber, making them difficult and labor intensive to separate from the lint. Eli Whitney’s achievement was to develop a saw gin that could more economically remove the seeds of fuzzy-seed cotton varieties.

since the mid-eighteenth century, were probably derived from perennial day-neutral forms of the Mexican race *lattifolium*, though not necessarily by direct introduction from Mexico into the United States.”

21 Regarding such efforts, Lebergott, *Americans*, p. 176 observed “Science was at work, sometimes. Coarse empiricism—try and try again—was at work, many times. (The distinction between the laborious laboratory work of the one and the random ventures of the other was not particularly obvious in the nineteenth century. Nor was it analytically clear at any time.)”

23 This American advantage changed over time as varieties developed in the United States were adopted in other regions. J. O. Ware, “Origin,” pp. 1-2.

24 Again, see Lakwete, *Inventing*, for an assessment of Whitney’s contribution. Variants of upland cotton could have naked, black seeds much like Sea Island cotton. But these upland strains were typically less productive and more disease-prone than the green or brown fuzzy seeded variants. A small number of alleles controlled these characteristics and the black trait is recessive. Thus, while it would be technically possible to produce an Upland crop that did not need a saw gin (or its equivalent), it would be associated with lower yields and subject to “invasion” by greenseed germplasm. In the green seed cotton, black seeds would occasionally appear (as Mendel’s laws predict). Frederick J. Tyler, *Varieties of American Upland
continued evolution in upland cottons as farmers attempted to adapt the standard Georgia Green Seed to different conditions. Some accounts maintain that by 1800 a new and improved variety, Tennessee Green Seed, had been developed in the Cumberland Valley.\footnote{Watkins, \textit{King Cotton}, pp. 100 and 254; Ware, “Plant Breeding,” pp. 658-59; \textit{De Bow’s Review} 12 (1852), 632-633.} Although the evidence is scanty, this variety appears to have rapidly gained favor outside the Valley because it could be picked about 20 to 25 percent faster than the older upland varieties.

There were at least two other parallel developments, one focused on Sea Island varieties and the other on Creole Black Seed varieties. In the late eighteenth century (circa 1786) a milestone was passed when high quality Sea Island varieties (\textit{G. barbadense}) were introduced into Georgia, possibly from the Bahamas or Jamaica.\footnote{A widely accepted account is based on a letter from Patrick Walsh of Jamaica who asserts he sent three sacks of seed to Frank Leavet (aka Levet) in Georgia. E. J. Donnell, \textit{Chronological and Statistical History of Cotton} (Wilmington, DE: Scholarly Resources, 1973), p. 48. (Note, first published New York: James Sutton, 1872). Smith’s account of the introduction of Sea Island suggests that although the shipment in question came to North America from Jamaica, it was native to Brazil. C. Wayne Smith, \textit{Crop Production: Evolution, History, and Technology} (New York: John Wiley, 1995), p.296. Although many historians have adopted the Walsh-Leavet story, there appears to be at least three other contemporary claims of first introduction. Other accounts have Sea Island coming to Georgia from the Bahamas, and it is possible it came to South Carolina several decades before the more generally dated introduction into Georgia. George Watt, \textit{The Wild and Cultivated Cotton Plants of the World} (London: Longmans, Green, 1907), pp. 272-73. Hammond, pp. 16-17. Stephens’ case for an anonymous introduction, probably from the Bahamas, is most persuasive. S. G. Stephens, “The Origins of Sea Island Cotton,” \textit{Agricultural History} 50: 2 (April, 1976), pp. 391-399. Theodore Rosengraten offers yet another possibility based on a source published in 1844. He maintains that Sea Island cotton came to Georgia from the Bahamas, but that it had originally come from the Near East, perhaps Persia. Theodore Rosengraten, \textit{Tombee: Portrait of a Cotton Planter} (New York: William Morrow, 1986), p. 50. The USDA reintroduced Sea Island type cottons into the United States early in the twentieth century from Egypt. The variety had earlier been introduced into Egypt from the Americas. G. A. Niles and C. V. Feaster, “Breeding,” pp. 201-231 in R. J. Kohel and C. F. Lewis, eds., \textit{Cotton} (Madison, WI: American Society of Agronomy, 1984).} Sea Island cottons soon prospered in the coastal regions of South Carolina and Georgia and became the basis for a fledgling export industry. Not only did Sea Island produce a much longer and finer fiber than upland varieties, its seeds were smooth and could be removed with the traditional roller gin. Persistent attempts to extend the range of Sea Island by acclimating it to upland growing conditions met with little success.

\textit{Cotton}, USDA Bureau of Plant Industry Bulletin 163, (Washington, DC: GPO, 1910), p. 17 stated that growers and breeders generally believe that “entirely naked seeds should be picked out and discarded from choice seed intended for planting.” He further reported the results from a test comparing fuzzy and naked seed from the same row of plants which revealed that the plants grown from fuzzy seed yielded 40 percent lint whereas those from naked seeds yielded 28 percent.
It would be a mistake to regard Sea Island cotton as either a uniform or an invariant product. Ware speculated that “more than one species and no doubt several varieties were brought in during the early period…. From these introductions the sea-island growers doubtless developed their own distinct varieties and strains….“ 27 Contemporary accounts are in accord with Ware’s view. As an example, South Carolina planter, Whitemarsh Seabrook, asserted in 1846 that decades of breeding had resulted in up to 15 sub-varieties of Sea Island cotton. 28 Just as early mechanical inventors whose genius stimulated the Industrial Revolution knew little of the laws of mechanics, these early breeders knew little of genetics or the science of plant breeding, but they were artists in knowing their plants. They sought practical ends and concentrated on the development of the long silky types of cotton that the English spinners of the time demanded. Their ideas were based on philosophical biology rather than on scientific biology, taxonomy, or genetics. They felt that environment had considerable effect in producing changes in plants but that heredity transcended all external influences, and that like did really beget like. With this philosophy as a guide, and expertness in observing, sorting, and selecting, they were equipped to build up a great enterprise through plant breeding. Among these growers a particular variety was considered the personal property of the originator and seed was not exchanged or sold unless something better was at hand. The result was the development of many special strains of the finest cotton the world has ever known. 29

It is common to think of crops and farm technologies as spreading from the east to west, but French colonists in the Gulf regions of lower Louisiana and southern Mississippi actually began continuous commercial production of cotton before planters in the Carolinas and Georgia. During the early 1720s, French settlers experimented with Sea Island cotton with limited success in a narrow band along the Gulf. The repeated failure of Sea Island elsewhere in the lower Mississippi Valley led farmers to test other options. By 1733 a variety imported from Siam called Black Seed or Creole had become the dominant cotton in the region. Like Sea Island, it had smooth seeds that could be separated from the lint with a roller gin. Creole was far more reliable and out-yielded Sea Island in this area but produced lower quality fiber. As with Sea Island, Creole was difficult to pick due to its small bolls and because the lint clung to the pods. But the Creole grown in the lower Mississippi Valley was superior in many respects to the Green

27 Ware, “Plant Breeding,” p. 658; Rosengraten, Tombee, p. 76.
29 Ware, “Plant Breeding,” p. 658.
Seed Upland cottons and commanded a far higher price. The Black Seed varieties first developed in the Gulf States moved eastward and apparently were widely diffused in the Carolinas early in the nineteenth century. At this juncture the story becomes clouded and at times seemingly contradictory. The published literature and primary sources dealing with cotton in the Southeastern states are replete with references to Black Seed varieties, but it is very difficult to know what was actually being grown, because a closer look reveals a far more complex and regionally diverse story. In her study of the Southeast, Chaplin notes that “Even after they standardized the kinds of cotton grown for sale, cultivators still had a crop that offered a dizzying array of varieties, resembling indigo (though not rice) in its range of types and qualities. Lewis Du Pre explained in 1799 that, although black- and green-seed cottons were the ‘extremes,’ myriad strains between these poles ‘run into each other, by almost imperceptible gradations.’”

A little known contribution by John Hebron Moore and Margaret Des Champs Moore confirms a more nuanced pattern. In the 1790s when South Carolina planters were first experimenting with commercial crops of upland cotton, they planted both Black Seed and Green Seed varieties. As examples, Evan Pugh planted a small crop of Black Seed in 1794, but did not begin to grow cotton on a significant scale until 1799 when he planted his first crop of Green Seed. Wade Hampton I planted 600 acres of Green Seed on alluvial lands near Columbia in 1799, and his success is credited with popularizing Green Seed throughout the Southeast. However, it took time for the word to spread because another South Carolinian, John Baxter Fraser, grew 40 acres of Black Seed on his thin pine-country soils in the Sumter region to the east of Columbia in 1803. In 1804 Fraser experimented with Black Seed and See Island, but when the Sea Island succumbed due to cold weather, he replanted ten acres in Green Seed. The next year he planted only Green Seed. This was six years after Hampton’s successful venture. In addition to yielding valuable information, these accounts provide a measure of our ignorance as to the spread of cotton varieties. First, it is unlikely that the all of “Black Seed” referred to in the Southeastern plantation records was derived from the Creole variety referred to in the Mississippi Valley records. There were other forms of upland Black Seed about which little

---

31 Chaplin, *Anxious Pursuit* p. 221.
information has survived. Moore speculates that the Eastern Black Seed was derived from the Sea Island cotton, but the fact that Fraser referred to both Black Seed (which produced in 1804) and Sea Island (which failed) at least offers a hint that what Fraser called Black Seed was not a Sea Island variety (only a hint, because planters in these early years of cotton culture often had little idea of what kind of seed they really had). In addition, Moore describes Frazer’s “Black Seed” as a short cotton about a foot tall, whereas the usual descriptions of Sea Island and the Mississippi Valley (Siamese) Creole depict a 6 to 10 foot tall cotton “tree.” Alas, this apparent inconsistency is not conclusive because it is conceivable that Sea Island (or Creole) cotton might be stunted on Fraser’s relatively infertile soils. 32

Letters found in the archives if Edmund Bacon who owned a plantation near Augusta Georgia indicate that Creole varieties were making their way to growers in the Southeast. On 3 December of 1807 Bacon wrote to his brother-in-law, Colonel Joseph Pannile, of Natchez noting that he was “very anxious to make an experiment the ensuing year with the best of your Orleans or Mississippi Cotton-seed.” Bacon speculated that “perhaps that planted in your Neighborhood is equal to any,” and request that the Colonel ship him “two hogsheads of the most approved seed in your country,” in time for planting by the first of April. 33 Although we cannot be positive, it is most likely that the seed in question would have been Creole Black Seed. Although the survival of such early documentation of the interregional flow of cotton seeds is unusual, there is no reason to suppose that Bacon was unique in his search for superior varieties or that he was the first to do so.

32 John Hebron Moore and Margaret D. Moore, Cotton Culture on the South Carolina Frontier: Journal of John Baxter Fraser, 1804-1807 (no place: privately printed, 1997), pp. 4-36, and telephone interview with John Hebron Moore, 20 April 2005. Recognizing that there were several distinct varieties of upland Black Seed and that a given variety might behave differently in different geoclimatic regions cotton helps reconcile the many disagreements regarding the relative yields of the Black Seed and Green Seed cottons. Other details of this story vary. For example, Moore notes that Creole was grown as an annual while others argue it was farmed as a perennial. C. Wayne Smith, Roy G. Cantrell, Hal S. Moser, Stephen R. Oakley, “History of Cultivar Development in the United States,” in C. Wayne Smith and J. Tom Cothren, eds., Cotton: Origin, History, Technology, and Production (New York: John Wiley, 1999), pp. 102-3.

33 Edmund Bacon papers, LSU Archives (Xerox). The flow of seed went in both directions, because in a letter to his sister Agnes Pannile of Natchez, dated 24 December 1815, Bacon noted that he had “procured Hogsheads in Augusta” and that he would ship her cotton seed of the “choicest-kind.”
After 1793, cotton production soared in response to the booming demand in Great Britain and technical improvements associated with Whitney’s gin, but in the second decade of the nineteenth century disaster threatened. According to Moore and a number of older accounts, “cotton rot” first mentioned around 1810, spread through Mississippi and neighboring areas over the next 15 years, causing devastating losses that threatened the survival of cotton culture.  

In response, growers in the Lower South imported seeds from Tennessee and Georgia and increased their plantings of Green Seed that was initially less prone to rot. In this region, the transition from Creole Black Seed to Green Seed varieties likely represented a case of technological regress, one dictated by the new environmental realities. The situation deteriorated further when the Green Seed varieties became susceptible to rot. It was at this juncture that the pace of biological innovation accelerated.

The first of a long chain of events that would revolutionize southern cotton production occurred in 1806. While visiting Mexico City, Walter Burling, a Natchez area planter, obtained seeds of a high quality cotton variety which he promptly smuggled out of the country. Burling passed the seeds on to a fellow planter and agricultural scientist, William Dunbar, who began the tedious process of experimenting and increasing the seed. The experimental process involved far more than just planting the foreign seeds...
and letting Mother Nature do the rest. According to Ware, “All Mexican stocks required some reselection for adaptation before satisfactory responses under Mississippi Valley conditions were obtained. Fresh seed from Mexico during the first year or two of planting was said to produce no more than one-half crop.”\textsuperscript{37} Dunbar also sent samples of fiber to Liverpool to be tested for spinning quality and received a positive response.

By 1820, southern breeders had out-crossed Mexican highland cotton with the Green Seed, Creole, and possibly even with Sea Island varieties, creating many new genotypes.\textsuperscript{38} Some of the hybrids that emerged represented vast improvements on the existing stock:

Its staple was longer and the grade of the lint higher than Creole or Green Seed. It ripened earlier in the fall than any other type then in cultivation in the United States, and it displayed a noticeable tendency to mature many of its bolls simultaneously. Even more importantly, it possessed exceptional picking properties. Its large four or five-sectioned bolls opened so widely upon ripening that their lint could be plucked from the pod more easily than any other known variety of the staple. Because of this unusual quality, pickers could gather three to four times as much Mexican in a day as they could the common Georgia Green Seed cotton. Most important of all, the Mexican strain was totally immune to the rot, the dreaded plant disease that was then destroying both the Creole and Georgia Green Seed crops in the Mississippi Valley.\textsuperscript{39}

Watkins was so impressed with the improved attributes of the Mexican cotton that he proclaimed that “From an economic point of view the introduction of this seed was second in importance to the invention of the saw gin.”\textsuperscript{40}

Numerous sources describe how an increasing number of growers in the Lower Mississippi Valley adopted Mexican cotton in the 1820s. Seed from Natchez evidently first arrived in the Gulf Hills region near Rodney, Mississippi in 1824. Ware reports that

\bibitem{37} Ware, “Origin,” p. 50.
\bibitem{38} Smith, \textit{Cotton Production}, pp. 296-97.
\bibitem{39} Moore, “Cotton Breeding,” p. 97; also see Gray, \textit{History}, pp. 689-90; Moore, \textit{Agriculture}, pp. 13-36, and Claiborne, pp. 140-43.
\bibitem{40} Watkins, \textit{King Cotton}, p. 13. Watkins probably took this comparison with the cotton gin from an 1851 account. See Thomas Affleck, “The Early Days of Cotton Growing in the South-West,” \textit{De Bow’s Review}, 10: 6 (1851), pp. 668-69. Gray, \textit{History}, p. 689 and Moore, \textit{Emergence}, p. 28 both reproduce this comparison with the saw gin. Watkins, \textit{King Cotton}, p. 13 notes that “the average day’s picking for a hand was 30 to 40 pounds of black seed and 75 to 100 pounds of the Tennessee green seed variety. At first a hand could pick 150 pounds of the Mexican, and this gradually increased to several hundred pounds.”
\end{thebibliography}
the Mexican cotton first appeared in South Carolina in 1816, but at this date the older varieties would still have dominated in that region and at least according to some accounts, it probably was not until roughly 17 years later that commercial seed of the Mexican hybrids was being marketed in the Southeast. According to Moore, in 1834 the rot that had earlier infected the Mississippi region evidently appeared in the eastern states badly damaging the Green Seed crop. This is credited with hastening the adoption of the Mexican hybrids. ⁴¹

Even in the Mississippi Valley the events surrounding the spread of Mexican cotton and the new hybrid varieties is more textured than the existing literature suggest. The Louisiana planter David Reese’s Diary offers a case in point. Reese’s commentary begins in 1819, and both his contemporary entries and his reflections of the years dating back to 1816, clearly document the destruction caused by rot. As an example, in September 1819 he lamented that he only expected one-quarter of a crop due to the ravished of the rot, and the next month he proclaimed 1819 the worst cotton season in memory. In 1822 he is still complaining about “Rot,” and from the description of the cotton—it was up to 9 feet in height with “Bowls some larger than Pigeon eggs”—he was growing Creole Black Seed (what he referred to as “Native” and “Louisiana” cotton). However, by this date he clearly makes reference to Tennessee cotton. The problem with the traditional account is that his Tennessee cotton was suffering more from the rot than the Native variety. In 1822 he was also experimenting with yet a third type of cotton: “The other cotton is growing fast with a considerable number large bowles [sic] some beginning to open.” This “other” cotton was probably grown from seeds that he purchased from Pierre Broussard in March of 1822. The following year he noted that “The Cotton from the seed bought from Pierre Broussard’s seems at this time as if it would grow as large as the Louisiana.” It is possible that the Broussard cotton was of

⁴¹ Moore, “Cotton Breeding,” pp. 97-98. The transition from black Seed to Green Seed to Mexican varieties in the Southeast was more complicated than some accounts suggest. First, in this region the original movement from Black to Green Seed around 1800 was not forced by the advent of rot as in the Mississippi Valley, and it appears that the transition in this region likely represented a technological advance (associated with the spread of the saw gin). In addition the motion of devastating outbreaks of rot in this area occurred at least as early as 1815. See Edmund Bacon papers, letter dated 24 December 1815, LSU Archives (Xerox).
Mexican origin because in 1826 Reese explicitly notes that he is growing the Mexican in field No. 4 and in part of field No. 5. But in spite of all of his past problems with rot he is still growing Tennessee and Creole varieties. As of May of 1826 he singles out the Mexican as “my best Cotton,” but by August he judged his best cotton to be in another field (we cannot be sure of the variety). Reese said little about picking and thus there is no forceful testimony in his records as to whether the Mexican was superior in this regard. For all the advantages touted in what we refer to as the older economic history literature, it is clear that the Mexican cotton did not always drive out the older varieties in one swift swoop.42

Notwithstanding these caveats, there is abundant contemporary testimony that the advantages of the new cottons was readily evident to many planters. As an example James Henry Hammond of South Carolina noted in 1833 that “Planted some Petit Gulf cotton and well pleased with it.” In 1834 he observed “Planted half my crop in Petit Gulf… Shale plant all Petit gulf hereafter.” The key point that flows from our investigations is substantially the same as that made by Moore and others: beginning around 1820 a movement was beginning that would transform American cotton varieties. In addition, from the mid-1820s to at least the mid-1830s there likely was a distinct difference in the modal types of cotton grown in the Lower Mississippi Valley and of those grown in South Atlantic states. Over this period the western cottons offered higher yields, were of better quality, fetched higher prices, and were significantly easier to pick.43 In addition it is likely that the spread of the new varieties widened yield and picking efficiency differences separating the nitrogen rich alluvial and black soil lands of the New South from the poorer lands in the hill country and the East. Although the early Mexican hybrids were evidently more productive than Green Seed on almost all types of soils, the productivity differential was far greater on good soils.

42 Reese, Reel 29, pp. 783-858; Reel 30, pp. 9-15. At the time of Reese’s account the Mexican hybrids were still being perfected, and in addition it could be that Reese and others of his generation would have gotten better results after learning better to plant and cultivate the Mexican varieties. For other archival accounts of rot devastating cotton see John Bisland papers (MS, 1817), Nathanial Evans, 1813. The experiences of John Walker of Kings and Queen County, Va. further illustrate that Mexican cotton was not always an instant success. Walker was experimenting with Mexican Cotton by 1827. We do not know what variety he subsequently planted but we can be sure that he was not completely taken with the Mexican because in 1834 he set out an area to test one-half gallon of “black cotton seed.” Stampp, Series J, Part 9, Virginia, Vol. 1?? and Vol. 2, 9 May 1834, p. 107 of diary (not of Stampp’s numbering).
43 Watkins, King Cotton, p. 13; Ware, “Plant Breeding,” p. 659.
Lest there be any doubt that the physical formation and fruiting qualities of the cotton plant might result in dramatically different picking rates, we offer photographs from the slave era or its immediate aftermath showing pickers working in low cotton and high cotton. The size of the bolls suggests that all of these photos show “modern” cottons as of the Civil War era. Neither the Green Seed nor Black Seed cottons would have had such large plump bolls. The descriptions of the early Black Seed varieties (which grew tall) depict small bolls the size of a pigeon’s egg.44

**Slaves or recently freed workers picking in low cotton**

![Image of pickers in low cotton](image1.png) ![Image of pickers in high cotton](image2.png)

**versus working in high cotton.**

By the early 1830s a succession of improved hybrids became commercially available throughout the South. Among the most popular were Petit Gulf introduced by Dr. Rush Nutt of Rodney Mississippi in the late 1820s (it was reportedly on sale in market towns across the Cotton South by 1833) and One Hundred Seed bred and

---

distributed by Col. Henry W. Vick of Vicksburg, Mississippi in the mid 1840s. In 1839 Vick began an annual process of having his most able slaves make special pickings of the finest bolls from the largest and most prolific plants. This cotton was ginned separately and then grown in isolated fields. Not trusting his slaves or overseers to do the job, Vick often ventured into the fields himself in search of valuable mutations and crosses. Vick personally selected the progenitor of the One Hundred Seed cultivar in 1843 from the particularly appealing bolls of a single plant that he had discovered while visiting another plantation in the Lower Mississippi Valley. He then increased this seed and began selling it locally a few years later. Petit Gulf and One Hundred Seed spread across a wide area and were noted for high quality, good yields, ease of picking, and rot resistance. Planters faced problems maintaining seed quality given the prevalence of cross-pollination in the field and the mixing of seeds at gins. The desire of planters to avoid exerting special care in seed selection and ginning encouraged the growth of specialized seed producers in Mississippi who shipped throughout the South.

In addition to Petit Gulf and One Hundred Seed, other important varieties produced by the antebellum Mississippi Valley breeders were Sugar Loaf (1843), Banana (<1848), Mastodon(<1849), and Boyd’s Prolific (<1847). Sugar Loaf, developed in 1843, was first in the line of cluster types (that is, the plant tended to have multiple bolls at each node on its short fruiting limbs, making the bolls cluster together). Boyd’s Prolific was another cluster-type cotton; it opened up the line of development of semi-cluster varieties (which possessed the clustering habit in a less pronounced form).

45 Moore, “Cotton Breeding,” pp. 95-104; Moore, Emergence, pp. 12-16. From reading Moore and other standard accounts, one might surmise that the rot disease wiped out the Green Seed varieties. To the contrary, in 1880 Tennessee farmers reported that “Green Seed” varieties were widely grown in the state. U.S. Census, “Cotton Production in the United States,” p. 99. Tyler’s 1907 survey of varieties notes that pockets of Tennessee Green Seed and other older varieties continued to be grown throughout the Cotton Belt. Ware, “Origins,” pp. 17, 45-46. There is a problem interpreting these accounts because there is no way of knowing if the Green Seed of 1810 bore a close resemblance to that of 1880 or 1907.

47 Moore, Emergence, p.13; Ware, “Origins,” pp. 12-14; Smith, Cotton Production, p. 297. Rush Nutt’s entrepreneurial talents were not limited to breeding quality cotton. Moore credits Nutt for being the first to use a steam engine to power a cotton gin around 1830. Moore, Emergence, p. 70.
Varieties such as Mastodon were highly esteemed in certain regions but were deemed “humbugs” in others.  

Colonel Henry W. Vick of Vicksburg, “the most persevering and the most successful of all the Mississippi planters in the art of perfecting cotton. (Lyman, 1868 p. 122)”

In his 1868 book, Cotton Culture, Joseph Lyman summed up the impact of the highland Mexican imports and their descendants:

Beginning with the year 1820, and from that time forward, various planters in different parts of the cotton growing States have devoted themselves to the development and sale of improved varieties of cotton seed, and certain styles of cotton have for two, three, or four years, enjoyed a great, though ephemeral popularity, and, then, as suddenly, been pushed aside for a new reigning favorite.

Antebellum observers were impressed and at times astounded by the high prices the new seeds brought in the market. Whereas, ordinary cottonseed sold for 25 cents per bushel (when used for manure), the Petit Gulf seed regularly marketed for twice as much. Seeds of choice varieties such as Sugar Loaf, Brown, Hundred Seed, Banana, Multibolus, and Prolific, “under ordinary circumstances, command from one to three dollars per bushel.” And when first introduced, Mastodon seed netted five dollars a bushel, Banana “at first sold for a hundred dollars a bushel [and] some paid ten cents apiece [again roughly $100 per bushel] for ‘Hogan’ seeds.”

We can take these seed prices as signals of the higher value that planters placed on the new varieties.

---

48 Watkins, King Cotton, notes (p.173) that M. W. Phillips of Hinds County, Mississippi considered Mastodon a humbug but that it was among the most common varieties planted in the late 1840s and early 1850s in Louisiana (p. 195), Texas (p. 217), and Arkansas (p. 243).
49 He continues: “The improvement of a cotton seed as a business, and sale of the improved varieties, has enabled quite a number of prominent and enterprising planters throughout the South to realize handsome fortunes.” Joseph B. Lyman, Cotton Culture (New York: Orange Judd, 1868), p. 121. Although this book was published in the postbellum period, its commentary focuses on antebellum conditions.
50 Lyman, Cotton Culture, pp. 121, 125. Lyman (p. 125) discusses the case of a planter who earned more profits from selling Mastodon seed than his entire crop of cotton. Also see Moore, 1956, pp. 100-102. Lest
To this point we have presented a brief case for the importance of biological innovation. The nineteenth century sources and the secondary literature indicate that there were many important advances, but the scattered and varied sources are not always in agreement on many of the details. To gain a clearer and more textured picture of the diffusion of new Mexican varieties and their impact we have developed a dataset on slave picking rates. Picking was the key bottleneck in the cotton production process. Gallman, Wright, and others have suggested that planters assessed how many acres they could pick and adjusted planting and crop mix decisions accordingly. Thus innovations that relaxed the picking constraint would have had dynamic implications leading to a growth in cotton acreage and an increased specialization in cotton production. While emphasizing the special importance of innovations that saved labor in peak load activities, we reiterate that picking efficiency was only one of the many superior qualities attributed to the Mexican hybrids—they also significantly increased output per acre (although the quantitative evidence on this is less abundant) and yielded a higher quality product.

The resistance of the Mexican cottons to rot contributed to the yield advantage and made them a more reliable crop. Once the older varieties became susceptible to rot it is most likely their yields and picking efficiency would have continued to decline if farmers had persisted in planting them. Thus comparing the observed yield and picking performance of Mexican cottons with “normal” crops of Black or Green Seed cottons would significantly understate what would have happened in a counterfactual world where the diffusion of the Mexican cottons had been long delayed. The observed trend in picking rates that we present later in this paper understates the true productivity impact of one think that antebellum planters were engaging in wild speculation, recall Peter Garber’s argument with reference to the Dutch Tulipmania. Given the capacity of bulbs and seeds to multiply, it may be entirely rational to pay “extraordinary sums” for the germplasm for new, rare plant varieties with desirable characteristics. Prices might be expected to fall as quantities multiplied. Peter M. Garber, Famous First Bubbles: The Fundamentals of Early Manias (Cambridge MIT Press, 2000), p. ix.

52 The scattered evidence on the yield advantage of the Mexican cottons almost always refers to the yields of seed cotton, and thus understates the true advantage. Gray, History, notes that “the older varieties yielded lint weighing only 25 per cent of the total weight of seed cotton.” p. 703. The lint-to-seed ratio of the Mexican cottons would have been at least 35 percent, implying a 40 percent premium following ginning on top of the substantial increase in the yield of seed cotton.
the Mexican cottons because an appropriate measure requires accounting for the presumed further decline in the productivity of the older varieties. In addition to these considerations our data on picking rates only bear on a part of a larger story because there were a number of important mechanical innovations that effected cotton production. To avoid interrupting the flow of our argument, these important changes are discussed in Appendix A.

**Assembling a New Data Set**

To assess the performance of their workers, many masters kept logs detailing the daily picking output of individual slaves. Absentee owners often required their overseers to keep such records so that the owners could better assess day-to-day farm activities, but many resident owners also caught the record-keeping bug.\(^{53}\) The data allowed for comparisons with past years, and helped set expectations for tasking the pickers. As Robert Fogel and Jacob Metzer suggest, the records were precursors to the time-in-motion studies initiated by Frederick Taylor and the “Scientific Management” movement in the early twentieth century.\(^ {54}\) Failing to meet picking standards had consequences. In

---

\(^{53}\) Absentee owners also desired the records to evaluate their managers and overseer and to prevent shirking, malfeasance, and so on. This motivation is suggested in the following passage in a 4 May 1834 letter from President Andrew Jackson in Washington to his son, Andrew Jackson, Jr., back in Tennessee: “My son, when you left me we had a right to believe our cotton crop would have yielded at least fifty thousand pounds baled cotton; we had a right from information to believe we would have 180 thousand in the seed, to 200. Now it appears that there was not raised more than about 114 to 120 thousand in the seed. I name this, that this fall you may guard against such imposition, and have a cotton Book on which must be entered the daily picking of each hand, and make the overseer responsible for the accuracy of the cotton Book.” John S. Bassett, ed. *Correspondence of Andrew Jackson*, Vol. V (Washington, DC: Carnegie Institution of Washington, 1931), pp. 263-64 accessed from Lexis-Nexis.

\(^{54}\) Fogel, *Without Consent or Contract*, p. 27; Metzer, “Rational Management,” pp. 123-50. The picking task was performed on an individual basis. Fogel and Engerman observe in *Time on the Cross*, p. 206 “(h)arvest operations do not appear to have offered the opportunities of division and specialization that existed during the planting and cultivation seasons…. In the absence of an interdependence that could be exploited to promote an intense rhythm of work, planters attempted to achieve the same objective by dividing harvest hands into competing groups. There were daily as well as weekly races, with prizes (bonuses) offered to the winning team and to the leading individual picker. There were daily weigh-ins of the cotton picked, and those who did not respond to the positive incentive had to face the abuse, verbal or physical, of the driver, if they fell too far below the expected pace.”

“The so-called ‘task method’ was still another means of promoting the intensity of labor during the harvest period. Under this method, slaves were assigned given plots of land which were to be picked each day. Intensity of labor was promoted by permitting the slave to use his time for his own purposes when the task was completed. One way of ensuring that the work was done well under this system was to
the 1830s, Dr. J. W. Monett of Mississippi asserted that after weighing an individual’s daily picking, masters would whip slaves for light or trashy picking.\textsuperscript{55} And we know that on several occasions, Louisiana planter Bennet Barrow ordered a whipping for all hands because the output was too low. On other occasions, Barrow sponsored picking contests with prizes.

Plantation managers recorded picking data in various documents including plantation journals, diaries, cotton books, ledgers, and the like. In one case we found the records for a part of a season in a letter from an overseer to the owner. Over time record keeping became more formalized with many planters employing bound account books with printed templates designed especially for this purpose. The most popular cotton account book was produced by Thomas Affleck, a noted nurseryman, experimenter, and farm journalist. The first edition of the \textit{Affleck Plantation Journal and Account Book} appeared in 1847. Within a few years he offered three different volumes—one for small plantations with up to 40 slaves, one for mid-size plantations with 80 hands or less, and one for plantations with up to 120 hands.\textsuperscript{56} In addition to the pages efficiently laid out for recording picking, the Affleck books provided forms for listing the slaves’ names, ages, and values, births and deaths, stock and equipment inventories, the weight of individual bales, and other valuable information. The entries and marginal notes often provide a detailed sense of the pulse of plantation life, including the days lost to rain, and

\begin{quote}
reassign the same plot to the same slave in each of the successive rounds of picking. Daily weighing of cotton also served as a check on performance.”
\end{quote}

Our examination of plantation diaries, cotton books, and Affleck-style accounts covering several hundred picking seasons has revealed several instances of competitions, but they seem the exception rather than the rule. “Weigh-ins,” as Fogel and Engerman describe the practice in their 1960-70s lingo recalling sit-ins, teach-ins, and be-ins, were far more routine and many times more common than prize competitions. Daily weighing also appears common even if the weights were not recorded.

\textsuperscript{55} J. W. Monett, “Cotton Crop” which was an Appendix (pp. 281-94) in Joseph Hilt Ingraham, \textit{The Southwest by a Yankee}, Vol. II (New York, Harper and Brothers), 1835. Monett writes: “After the weighing is over, and the baskets are emptied, or turned bottom upward, upon the scaffolds, the overseer takes the slate, and examines the weights attached to each name. Those who are found to have brought in less than their usual quantity, unless for good reasons, are called in the order of their names; the individual advances, and if his reasons are insufficient, he is ordered to lie down upon his face, with his back exposed; when he receives ten, twenty, or fifty stripes with the whip, according to his deserts. In this way the overseer goes over the list, punishing only those who have idled away their time…. No one knows that he is to be punished until his name is called, when he has an opportunity of giving his reasons for his imperfect day’s work.”

whether or not the slaves worked a full or half day, whether the slaves worked on Saturdays, and the like. Only rarely did the slaves pick cotton on Sundays. The records also indicated which slaves were sick on a given day and which were assigned to other tasks such as making baskets, cutting timber, tending other crops, hauling, and working in the gin. Of course the overseers and owners differed significantly in their attention to detail, but in many instances when the key information was not recorded in the Affleck volumes, we were able to extract it from surviving diaries and other farms journals.

Figure 2 shows an example of a “user friendly” page from an Affleck book—one that is legible, reasonably complete, and in this lone case one that was already scanned into a machine-readable form. This record comes from the Eustatia Plantation in Mississippi. 57 These records detail the picking of nearly 60 slaves throughout the 1860 picking season. (But there are many records for other planters, so many that it is hard to retain any romantic notions of a sleepy plantation system run by pre-capitalist masters.) Note that this page shows the overseer’s calculations of the daily totals. Such sums prove valuable in allowing us to check the accuracy of our work although in many cases, the record keepers’ sums are not quite right. Obviously, our problems and costs soared when the pages were harder to read, when the overseer changed the order of the names from page to page, and when the data were incomplete.

We entered these data on individual picking into Excel spreadsheets. 58 In collecting the data we were especially careful to avoid entering false positives. At present we have about 400,000 individual picking entries, spanning the years from 1811-1862. These records include data from 61 separate plantations, with many more plantations to still be entered. The quantity and quality of the data differ greatly from plantation to plantation. For 18 plantations we have data for only one picking season or for part of a season. At the other extreme we have data for 22 years for the Leak plantation located in Tippah (now Benton) County, MS. We have only 60 entries for the Bassett plantation in Hanover County, VA, whereas we have over 10 thousand entries

---

58 To expand coverage, especially for the earlier period, we are also developing a second class of observations that utilize plantation records displaying only daily picking totals and aggregate numbers of pickers. Some plantations report only such data and others do so for selected periods, typically early in the season. Note such aggregate data provide no means of controlling for the composition of the picking crew.
each for five different plantations. The Leak plantation sets the standard for the most entries for a single plantation at 79,602 and for a single season at 5,454.

Our sample is concentrated in the Mississippi Valley with 24 plantations located in Mississippi and 14 in Louisiana. The years of coverage for these two states stretch from 1811 to the end of the Civil War with at least some data for almost every year in this period of over one-half century. The data become more abundant in the 1850s. Over all of the states, we have 8,887 observations for the years before 1820; 16,926 for the decade of the 1820s; 39,258 for the 1830s; 104,362 for the 1840s; 175,915 for the 1850s; and 52,942 for the 1860s. The disruptions caused by the Civil War are evident as the records become less abundant and many males disappear from the samples.

Many of the records we used are found in the University Publications of America microfilm series *Records of Ante-Bellum Southern Plantations: From the Revolution through the Civil War*, edited by Kenneth M. Stampp. We owe a great debt to Kenneth Stampp and others associated with this project for making accessible the records of about 1500 plantations. But the UPA project overlooked many plantation records. To expand our sample we searched the catalogs and consulted with special collection librarians in dozens of university, state, county, and municipal libraries located across the South. There have been far more dry holes than gushers. The collections at Louisiana State University, the University of Mississippi, the Mississippi State Archives, the University of North Carolina, the University of Texas, and Duke University have proved particularly rich. Some of our data came from private individuals whom we identified on the web through their postings of genealogical research.

We are in the process of converting the individual slave picking data to Stata files so we can take full advantage of the panel dimensions of the micro data and more fully capture the nuances and implications of the changes over time. The aggregate data will have to suffice until these datasets are ready.
Figure 2: Sample from Eustatia Cotton Book
Summary Results on Picking Productivity

Figure 3 shows our summary results for the 1811-1862 period. These results are both preliminary and incomplete, but the panels of the Figure reveal a clear upward march in picking rates roughly in conformity with the claims of the broader economic history literature. Each data point represents the mean or median amount of cotton picked per day for a “plantation year.” Thus a plantation with 300 entries covering only part of the picking season has equal weight as a plantation with 5000 entries spread across the entire season. The labels of the plantations indicate their locations by state (MS=Mississippi, LA=Louisiana and so on).

The panels in Figure 3 for the means and medians also include two sets of time trends which were calculated from the regression results displayed in the Table 3. The first set estimates the time trend including linear and quadratic time trends without any further adjustments. By these estimates, the mean pounds increased over 2 percent per annum, rising from 43.4 pounds in 1811 to 121.0 pounds in 1860. This represented an increase of 2.8 times. The median pounds picked grew by similar magnitudes. These increases are not as large as the purported quadrupling from 50 to 200 pounds over the 1800-60 period as suggested by Legergott, but the changes in output per day are, nonetheless, highly impressive. For both the means and the medians, the quadratic terms indicate the grown process was slowing down.

The second set of time trends attempts to control for the effects of changes in plantation size as measured by the average number of pickers working per day. Across the plantations in our current sample, the average number of pickers increased by 1.3 percent per annum, rising from about 17.3 hands in 1811 to 32.2 in 1860. In our sample, plantations with larger picking crews tended to have higher rates of picking per person (which is consistent with economies of scale, positive correlations between size and managerial efficiency, and other explanations).\textsuperscript{59} Controlling for the (log of the) number

\textsuperscript{59} The measured effect of (the log of the) size of the average number of pickers appears quite large at 0.19. This would imply a doubling in the size of the crew leads to a roughly 20 percent increase in daily output per picker. Note that most of our plantations are larger than the average southern farm and, given the available data, we include no free labor operations. This result is interesting because by all accounts
of pickers reduces somewhat the estimated time effects; the mean pounds by this measure
increase by 1.7 percent per annum. This is still rapid enough to yield a more than
doubling in the picking rate over the 1811-1860 period. (The results also suggest that the
measured increase in the number of pickers can account for about 15 percent.)\textsuperscript{60} The
adjusted time trends in the panels hold the number of pickers constant at their (geometric)
mean level.

The Figure and regression results also reveal an enormous variability in the data
across plantations, regions, and nearby crop years. The R-squares are relatively low, and
the variance even within a given decade, such as the 1850s, is high. (See below for a
breakout of the plantations in the Lower Mississippi Valley, excluding Leak who is an
outlier both in the sense of having low picking rates for the region and being located in
the uplands far off the Mississippi River.)

The above analysis compares the picking rates of a number of plantations across time and space. In addition, we would like data from specific plantations that clearly record picking rates before and after the diffusion of the new biological technologies. The records of the Evans plantation, which offer picking data for the second decade of the nineteenth century and for 1866, provide this perspective. The diary of Nathanial Evans indicates that he was planting Creole Black Seed in the years 1811-1817. The individual picking records for this period (1811-13, and 1817) show that the mean quantity of cotton picked per slave for these four years was 70.8 pounds. By the early 1820s, Evans was experimenting Tennessee and Mexican varieties, but no evidence on picking rates has survived. However, we can connect the early pre-Mexican picking rates with cotton picking data for 20 freedmen and women for the 18th and 19th of October, 1866. Here we have data for the same location separated by 50 years. For these two days the mean picking rate was 157.3 pounds or 2.2 times that recorded in the pre-Mexican era. Given that picking rates varied significantly over the season and October would typically be a peak period, it is important to fine-tune our comparison. In the 1811 to 1817 period the mean picking rate during the months of October was 74 pounds. In 1866, 12 of the 40 observations exceeded 200 pounds and one exceeded 300 pounds. By comparison in October of the four years for which we have data in the earlier period only two out of the 1308 observations exceeded 200. It is most likely that these comparisons significantly understate the differences in picking rates had we had data comparing the 1810s and the late 1850s when slavery still existed. Data for several other plantations show significant drops in picking rates in the later stages of the war and in the immediate post war years during the transition to a free labor force.61

Disaggregating the Data: Age, Sex, and Season

One can raise many objections to these preliminary results based on the aggregate data, but it will be best to wait to make refinements until the disaggregate data are

---

61 This finding is in line with Ralph Shlomowitz’s depiction of unsettled labor markets during the post war years. Ralph Shlomowitz, “The Origins of Southern Sharecropping,” Agricultural History, 53 (July 1979), pp. 557-575.
available. Disaggregating and building a panel of the individual data will help us address the many problems inherent in the numbers presented in Figure 3. For example, we know children did not pick as much as adolescents or adults. For many plantations we have the ages of the slaves. With this information we can make reasonable adjustments in comparing rates over time and between plantations. In addition we should be able to provide firmer estimates of the relative productivity of children at different ages. In a similar fashion we are interested in the gender division of labor. Many accounts assert that women were better pickers than men. We shall see.

The data also need to be adjusted for seasonality. Picking rates tended to be much higher at the peak of the season when the crop was ripening fast. The general pattern appears to be that rates are relatively low in August, then rise in September, October, and November, before dropping off sharply in December. It is important to determine if the data show any changes over time in the length of the season, the timing of the peak periods, or in the relative intensity of the peaks. Seasonality adjustments will also affect the relative productivity of children and women versus adult men. This is because at the start and end of the picking season and during other periods when the cotton crop was light, it was common for males to perform non-picking work (i.e. ginning, pressing, hauling, cutting timber and clearing land, etc.). In addition, according to Gray “It was customary to pick a field three times, the several pickings being designated successively the ‘bottom,’ ‘middle,’ and ‘top,’ crops. The middle picking furnished the largest product....” For these reasons to compare the efficiency of men and women requires us to know when they are picking and to essentially compare days when both genders worked.

We also must check how representative the plantations in our sample are. We intend to link these establishments with the censuses of 1850 and 1860 to improve our understanding of this issue. We suspect that plantations in our sample will be larger and more oriented to cotton production than the typical operation in the census, but will be roughly comparable to the types of plantations with surviving archival records.
Diffusion of Easy Picking Cotton

It would also be desirable to link the picking records with the plantation diaries to determine better which cotton varieties the plantations were actually growing. There are many claims in the history literature about the diffusion of picker-friendly cotton. With more entries we hope to be able to better document this process. At this point we do not see any distinct breaks in the data for the plantations for which we have a long spread of years starting early enough to be reasonably confident that the plantations were initially growing black or green seed varieties. The conversion process appears to be more gradual, consistent with the planters experimenting with a new variety and gradually adopting it.

Conjectures about the Impacts on Southern Development

Two implications of the increased picking efficiency are clear. The set of technological innovations raising picking rates would (1) improve the competitiveness of U.S. cotton in world markets and (2) lead the ratio of the price of slaves to the price of cotton to rise. Most other implications become entangled in assumptions about the elasticity of the long run demand curve for cotton, the nature of the production functions, and a host of other conditions.

One difficulty with drawing other firm implications is that the voluminous empirical literature on the cotton markets has failed to generate much consensus about the precise price-elasticity of demand for the U.S. cotton crop. Table 4 shows a sample of the estimates. Wright’s estimates “put the elasticity of demand at roughly 1.0 during 1830-1860, 1.5 for the period 1866-1895, but back to 1.0 for 1879-1913.” Wright’s earlier (1971) study as well as Surdam’s 1998 investigation indicate a more inelastic demand over the 1830-60 period whereas Irwin’s 2001 working paper supports a more elastic estimate for the U.S. product. Irwin does take an important step by accounting explicitly for quality differences; he adopts an Armington framework that treats different countries’ cottons as differentiated products. One complication for our quest to examine

---

the impacts of the introductions of the new varieties is that none of these studies considers changes in the quality of the U.S. crop. It is worth noting that only Surdam’s study suggests that demand was sufficiently inelastic to generate the conditions of immiserating growth, implying the increased productivity reduced cotton incomes.

Sources and Notes:

Surdam’s econometric estimates p. 131 relating the US crop and price over the 1831-61 period also yields an elasticity of approximately –1.

**The Effect on Cotton Production and Prices**

The increase in picking efficiency should have lowered the cost of producing cotton. There would have been super normal profits to early adopters, but these should have been gradually competed away as cotton supplies increased. Given that diffusion of the new seeds probably took decades and that there was a flow of new innovations over
time, it is possible that planters near the center of innovation maintained some advantage for decades. The long run outcome would depend on the long run elasticity of demand. Assuming that cotton farming was competitive in the output market, the observed record of cotton prices falling at a time of rapidly growing supply implies individual firms (plantations) on average were moving toward new lower cost equilibria.

The increase in picking rates should have increased the competitiveness of U.S. cotton producers relative to those in the West Indies, the East Indies, Brazil, and Egypt. Over the period from 1820 to 1860, the U.S. share of the world commercial market for cotton (as measured by consumption in Europe and America) increased from roughly 67 percent to over 80 percent. Figure 4 graphs the relevant data. The growing dominance of the U.S. South in this important market depended on the expansion of productivity in its cotton sector. Given that the learning was location-specific, adaptations made to fit the environment of the U.S. South very likely did not immediately spillover to benefit competing regions.

Figure 4: Shares of Cotton Consumption in Europe and America, 1821-60

The Effect on Slave Prices

As with any input, the rental price for slaves was a function of a derived demand dependent on their marginal productivity and the price of the output, in this case cotton. The increase in picking efficiency would have increased the marginal product of slaves in cotton, and all else equal, increased slave prices. It is possible that the increased efficiency could have led to a fall in the price of slaves if the price of cotton had fallen relatively more than the increase in slave productivity. The historical movement in slave prices indicates that the price-elasticity of cotton demand was sufficiently high that this did not happen.

Economies of Scale, Crop Mix, the Gang System, and Geography

Especially pertinent to our analysis is Gavin Wright’s finding that a systematic difference in the mix of crops grown on plantations and family farms within the South explains much of the labor productivity advantage attributed to the plantation system. Wright argues that 1859 (the census year for which the estimates were made) was an exceptionally good year for both cotton yields and cotton prices, and thus plantations which were more specialized in cotton production than were family farms appear to have been more efficient. In addition, Wright and others have noted that plantations occupied better land than family farms.63 Our discussion of the distribution of cotton varieties bears significantly on this debate. There is abundant commentary in the agronomy literature that the superior yielding varieties grown on the fertile bottom lands systematically differed from those grown on less fertile soils. Cotton was not cotton. By overlaying soil quality maps atop our picking data and holding all else constant, we should be able to provide a fresh perspective on many of the questions raised in this prolonged debate.64

64 The plantation-family farm efficiency measures assume one average price for cotton. The plantations on average produced higher quality and higher priced cotton so the estimates understate the plantations’ true advantage. However, the higher quality and price was a function of the geography, good management, and the varieties grown, not of the presumed economies of scale inherent in coerced gang labor. Fogel and...
Our emphasis on the importance of biological innovation points to an advantage of large plantations that hitherto has gone unnoticed in the mainstream literature. The plantation system did offer an important economy of scale that had much more to do with the hum of bumble bees than the purported rhythmic sound of hoes working in unison. Plantations—because of the physical size of the production unit—could isolate prized cotton varieties from other varieties and thus reduce the problem of cross pollination. Wealthy planters could also more readily afford to act as local experiment stations, investing to develop better seeds and practices. As a result plantations were much more likely to be able to maintain the purity of superior seed than small farmers, giving the plantations a dynamic, self reinforcing productivity advantage over small producers.65

Taking a longer view and delving into the sources of southern agricultural productivity in 1859, suggests a different perspective from that found in the existing productivity debate. As our recent work on wheat demonstrated, northern farmers were constantly changing varieties to ward off the evolving threats from insects and diseases and to make profitable the expansion of the wheat frontier. Without these changes, northern land and labor productivity would have fallen substantially below that which history recorded. But for all the importance of biological innovation in wheat production in the antebellum years, there were no breakthroughs that so fundamentally and directly changed land and labor productivity as the introduction and subsequent diffusion of the improved Mexican hybrids. Hence, whatever one’s view on the interregional productivity debate, the South’s relative advantage over the wheat-producing North in 1859 (if it had one) stemmed in large part from the different regional patterns of biological innovation over the previous five decades.

Engerman have taken issue with many of Wright’s arguments noting that there is neither direct evidence nor contemporary commentary supporting the contention that output was exceptionally high in 1859. Robert W. Fogel and Stanley L. Engerman, “Explaining the Relative Efficiency of Slave Agriculture in the Antebellum South,” pp. 247-49. To support our point about the lack of attention to productivity changes over time, there is very little mention of this issue in the 4 volumes of Without Consent or Contract. The exception is Jon R. Moen’s contribution “Changes in the Productivity of Southern Agriculture between 1860 and 1880,” pp. 320-50. Moen does not consider biological inputs.

Although our evidence lends support to Gavin Wright’s view that a number of factors besides the slave labor system could account for the proposed relative efficiency of the plantation system vis-à-vis family farms, we disagree with him on another issue. In *Old South, New South*, Wright develops the landlord and labor-lord taxonomy. Wright argues that because so much of their wealth was tied up in slaves, plantation owners had little incentive to maintain the productivity of their land and took few steps to do so. Whatever the analytical ambiguities of this position, it does not account for the enormous success southern planters achieved in developing and adopting a succession of new cotton varieties that dramatically increased both land and labor productivity. In this arena it appears that southerners were at least as active as (and more successful than) their northern counterparts.

**New Perspectives on Western Settlement**

The territorial expansion of the cotton-slave frontier was one of the most controversial issues of the antebellum era, with claims and counter claims about the importance of new lands in preserving the political and economic power of the Slave South. Much of this literature lies at the foundation of the early debates over the profitability of the slave system. For all the discussion of the political and economic implications of the spread of slavery, there has been no precise measure of the actual spread of cotton culture and little understanding how technological forces help explain the pattern of settlement of the Cotton South.

Momentarily stepping away from our picking sample can offer a fresh perspective on the geographical movement in cotton production. In the early 1790s, U.S. production was concentrated along the coast of Georgia and South Carolina. By 1839, as the data in

---

Table 5 reveal, the geographic center (median) of the production of upland cotton was near Greensboro in west central Alabama. And by 1859, the center was across the Mississippi-Alabama border. (Note that it was not until the 1880s that the median geographic center of wheat production was west of this longitude.) The speed of this westward movement before the Civil War is all the more impressive when one realizes that over the entire period from 1860 to 1920, the geographic center of cotton production remained within the boundaries of the state of Mississippi. Valuable information on the antebellum years is offered in Figure 5. It employs Watkin’s annual data on commercial cotton output by state to chart the changing regional distribution of production over the 1800-1860 period.\footnote{Watkins, \textit{King Cotton}, passim.} As the Figure shows, the shift away from the Atlantic Seaboard states (VA, NC, SC, GA, FL) begins in earnest in the early 1810s. By 1833, their share had fallen from over 95 percent to less than one-half of output and by 1859 to less than one-quarter. Did biological innovation play a significant role in this process?

\footnote{Watkins, \textit{King Cotton}, passim.}
The existing literature maintains that the West enjoyed a productivity advantage because the land in its vast alluvial basins was inherently better than the land common in the East. Moreover, the virgin land in the West had not yet been mined of its nutrients.
Figure 5: Regional Distribution of U.S. Cotton Production, 1800-60
as had purportedly occurred in the East. The long-standing explanations of East-West productivity differences are seriously deficient. The rapid shift in production in the years before 1833 occurred precisely when western cotton producers enjoyed a significant varietal advantage over eastern producers. With more data we hope to better document the movement in the East-West picking efficiency gap. (It is important to emphasize that the picking data tell a larger story, because they are almost surely correlated with improvements in cotton yields and quality.) As the new varieties gained wider acceptance in the East in the 1830s the gap might have narrowed, but not necessarily because biological innovations continued in the West. Moreover, the new biological technologies almost surely were not “soil neutral;” they represented an improvement on a wide spectrum of soil types, but they were particularly suited to the most fertile lands. The large plantation regions of the West had better soils to start with, but in a sense biological innovation made these soils increasingly better.

Figure 6 takes a preliminary pass at some of these issues by decomposing our sample to look at picking rates in the fertile Mississippi Valley. The sample shows all plantations in Mississippi and Louisiana except the Leak Plantation which we know to have been located in the north-central part of the state away from the Great River. Over the period 1811 to 1860, the picking rate (the unadjusted time trend) did increase faster than for the entire sample, roughly tripling. The annual growth in picking efficiency was 2.62 percent a year. This is about 0.5 percentage points higher than for the sample as a whole. With more data we hope to better quantify the dynamics of regional differences in picking efficiency.
Conclusion

This paper demonstrates the enormous gap separating neighboring cultures—one largely static, associated with cliometrics and the other dynamic, associated with a more literary tradition. The rough parameters of our argument on the role of new cotton varieties in increasing slave picking efficiency has long been a part of the standard historical treatments of the Cotton South. We strongly suspect that little that we have said on this basic issue would have come as a surprise to Watkins, Gray, or Moore. Nor would it have stunned Lebergott, Parker, Hayami, or Rattan, who are among the few economists to have peeked across the cultural divide. In our attempt to bridge the gap, we have enhanced their stories with evidence on the evolution of cotton varieties drawn from the agronomy literature, and we have added a measure of precision to long-standing speculations. Most importantly we have sought a better understanding of the dynamic forces that propelled cotton productivity growth, and in doing so, we hope to cast light a wide array of cross-sectional issues. Our scaffolding is built on the solid foundation of
over 400 thousand picking samples. We are far from finished; there are more data to be gathered and more sophisticated tests to be made. However, at this stage some preliminary findings seem apparent. Over the 50 years preceding the Civil War, picking efficiency increased at about 2.0 percent a year. The increase in picking efficiency was correlated with yield and quality improvements that further added to the incentives to grow cotton. These changes help make sense of the long run movements in cotton and slave prices. They also provide new perspectives on many long-standing issues, including the westward march of cotton production, the movement of slaves out of industrial and other urban pursuits into cotton, the role of scale, geography, and other factors in determining productivity. A fuller examination of these issues is on our agenda.

To put the pre-Civil War increase in picking efficiency into perspective, the early (circa 1860) mechanical reaper, which represents the textbook example of an antebellum labor-saving mechanical innovation, increased wheat-harvest labor efficiency relative to using a cradle by roughly 50 to 100 percent. The data on the impact of Mexican hybrids suggest that their impact on cotton harvest efficiency likely surpassed that of the reaper on the grain harvest in the antebellum era. The total impact of the Mexican hybrids would of course have been even greater because of their effects on yields and cotton quality. The mechanical reaper had no parallel impact on either yields or quality. But the Mexican cottons did have one important point in common with the reaper and many other mechanical innovations. The new easier picking cotton varieties helped smooth out the peak-load labor demands so that the labor hours needed for the harvest more closely approximated those needed for non-harvest tasks. This led to a decline in the often-heard comment that farmers planted more cotton than they could pick, and (as with the diffusion of the reaper) it presumably led to an increase in acres planted. These were some of the ways that biological innovations were reshaping the opportunities

68 In actuality it was the reaper and the use of additional horsepower that yielded this result. 
69 Mechanical technologies were not static in that the reaper of 1860 represented a step in a sequence of developments that eventually led to the grain combine. But the biological learning of the pre-1860 era also laid the foundation for later spinoffs important in the development of American agriculture.
cotton farmers faced, fundamentally altering the economic landscape of the antebellum South.  

A number of scholars who are clearly aware of both the biological and mechanical advances of the antebellum era somehow persist in dismissing them as insignificant. For example Charles Post recounts the bare outlines of the importance of Petit Gulf and of mechanization (p. 296) and then repeatedly makes inexplicable assertions to the effect: “There is no evidence of systematic and widespread introduction of labour-saving technology in cotton production.” Charles Post, “Plantation Slavery and Economic Development in Antebellum Southern United States,” *Journal of Agrarian Change*, Vol. 3, No. 3 (July 2003), pp. 289-332; quote from p. 300.
Appendix A

Important Antebellum Mechanical Innovations

As noted in the text, the antebellum period witnessed important changes in mechanical technologies in cotton as well as biological technologies. In particular there were quality improvements in both plows and hoes with the movement to steel implements after 1840, and a shift away from using the relatively labor intensive hoe for some tasks. We have to look no further than Gray for considerable evidence of mechanical advances. For example, “In the earlier years there was a tendency to make more use of the hoe than in later years.... There was a gradual adoption of implements suitable for shallow cultivation, such as the scraper, skimmer, and sweep. The skimmer and sweep greatly economized labor in cultivation....”

Gray offers a quantitative sense of the importance of some of these advances. “The scraper, adapted to shaving the bed close to the cotton, economized the amount of hoeing. According to Dr. M. W. Phillips, by employing the scraper it was practicable to clean and thin 1¼ acres daily per hand, as compared with only ¾ acre by other methods.” Many planters also adopted mechanical seeders in the antebellum years which saved labor at seeding time. The trend was to plant less seed, more carefully, “so as to avoid much of the laborious thinning and cultivation.” This increase in the use of more tools and more efficient tools underlies Whartenby’s conclusion that output per worker about doubled between 1800 and 1840. The key message for interpreting our work is that the data on picking efficiency, as significant as they are, only capture part, maybe even a small part, of a larger story of technological innovation on antebellum cotton farms.

71 Gray, History, p. 701.
72 Gray, History, pp. 700-02.
73 Gray, History, p. 701. Adjustments in the time of planting, the density of seeding, and in plowing practices, all effected land productivity. Early in the nineteenth century, southern farmers generally plowed up and down hillsides, thus unnecessarily creating horrible erosion problems. Enlightened farmers such as William Dunbar experimented with the development of horizontal plowing techniques and campaigned to convince his reluctant neighbors to adopt his new system. Horizontal systems (with gentle slopes and drainage ditches) continued to be perfected and adopted over the pre-Civil War era. The major mechanical improvements of the era occurred in post-harvest operations that included the ginning, pressing, and transporting of cotton. These all added to the productivity growth of the industry. Gray, p. 689-70; Moore, Agriculture, pp. 46-47; Moore, Emergence, pp. 30-34, 50.
Another Method of Estimating Productivity Gains

In addition to the evidence on picking efficiency presented above there are many claims as to the total amount of cotton a worker was expected to pick in a year. Interpreting these data is even more difficult than assessing the daily data because meaningful comparisons require knowledge of how many hours a picker worked in the harvest, the conditions of the fields, the type of cotton, the extent of coercion and/or incentives offered, and the age, sex, and health of the worker. Acknowledging these caveats, there is ample testimony that annual picking output per worker went up substantially due to the introduction of Mexican cotton. As an example, Moore notes that “Farmers, who in 1800 had hoped to average two 400-pound bales to each field hand, by 1837 were trying to produce crops of six to eight bales to the hand.”\footnote{Moore, \textit{Agriculture}, p. 46.} Moore further notes that “in the years 1833 and 1836 Richard Nutt, son of Dr. Rush Nutt, averaged nine bales of cotton to the hand, a record almost equaled by his brother.”\footnote{Moore, \textit{Agriculture}, p. 215, fn. 26.} Moore’s account, based as it is on a few data points, appears to paint an exceptionally rosy picture of slave productivity.

Although there are many other claims of similar high bales per slave achievements, the most thorough investigation of the issues is probably James Foust and Dale Swan’s 1970 analysis.\footnote{James D. Foust and Dale E. Swan, “Productivity and Profitability of Antebellum Slave Labor: A Micro-Approach,” \textit{Agricultural History} 44: 1 (Jan. 1970): 39-62.} This research suggests that Moore’s antidotal evidence of bales per hand was not representative. Foust and Swan examined the labor-input and cotton-output data in 1849 and 1859 for a sample of farms in 74 cotton-producing counties. Both the 1849 and 1859 samples contained well over 500 cotton producing farms. They (and Sutch before them) did not rely on direct, individual observations of picking rates as we do, but rather they calculated the output per slave using farm-level cotton output in bales divided by one half of the number of slaves on a given plantation.\footnote{Richard Sutch, “The Profitability of Ante Bellum Slavery—Revisited,” \textit{Southern Economic Journal} 31 (April 1965): 365-83. Foust and Swan assume that the “field hand equivalent rate” was 0.50 in both years. This adjustment is an attempt to account for children, old folks, house slaves, etc.} They found that bales per slave for the whole sample increased from 1.59 in 1849 to 2.11
in 1859. On “Alluvial” lands the increase was from 2.07 to 2.78, for their “Other New South” region bales per slave went from 1.49 to 2.64, and for their “Old South” region it went from 1.47 to 1.48. One might question how sensitive these results are to the various assumptions underlying their estimates and how sensitive the results are to the weather and other conditions in the two years studied. All of these caveats could influence the credibility of their findings on the change in bales per slave over the decade, but probably not our general proposition that Moore’s literary account gives a misleading impression of general conditions. Our method of examining individual picking rates over time requires no heroic assumptions and is relatively insensitive to short run weather shocks. We expect our findings will correlate well with independent evidence on the timing of the introduction of the new varieties.  

78 Perhaps the most interesting aspect of Foust and Swan’s study is not what they said but what they omitted. They offer no systematic evidence as to why cotton per slave increased beyond speculating that it might be due to a shift in production to larger plantations that could capture economies of scale.
