The Effect of Quits on Worker Recruitment: Theory and Evidence

Abstract

Recruitment effort by a firm can signify one of two things: a desire to expand or a need to replace workers who have quit profitable positions. Standard matching models with on-the-job search treat these two recruitment activities as the same. Yet, we provide empirical evidence that suggests these two activities differ in the sense that, all else equal, an establishment is much more likely to post a vacancy and hire a worker if someone has quit a position at the firm. Our evidence is robust to a variety of controls, including establishment fixed effects. One natural explanation for this is that workers who quit leave behind firm-specific physical and organizational capital, thereby making replacement hiring less costly than the creation of a new position. To this end, we develop a matching model with on-the-job search and multi-worker firms that differentiates between the cost of creating a new position and the cost of adverting for an existing opening. The model naturally creates a distinction between worker and job flows and, through endogenously-determined thresholds for separations, worker replacement and position creation, produces rich firm-level employment dynamics that are broadly consistent with the establishment-level empirical evidence.

---

1 Introduction

Workers often quit their jobs to take a better offer. There is now evidence (e.g., [20]) that job-to-job transitions are an important part of wage gains over an individual's life cycle. There is also evidence ([10], [17]) that these job-to-job transitions are an important part of aggregate employment dynamics. To date, however, the literature has little to say about the job that a quitting worker leaves behind. In this paper, we aim to fill this gap.

Standard matching models with on-the-job search (e.g., [19], [14], or, more recently, [16]) make no distinction between a vacancy that is created because a worker quit and one for a newly created position. If existing positions entail some firm-specific organizational or physical capital left behind by a quitting worker, the decision to replace her will differ from the decision to create a new position. Given the difference in existing capital, one would expect a hire to proceed a quit more often than it reflects the creation of a new position. We explore whether this holds both empirically and theoretically.

The relationship between quits and recruitment is, of course, confounded by the fact that decisions to quit or hire are often endogenous events influenced by the business climate of the firm. Firms with grim prospects are more likely to experience a quits, less likely to replace those quits and more likely to lay off additional workers. Firms with bright prospects are less likely to experience a quit, more likely to replace those who leave, and more likely to hire additional workers.

We start by examining the impact of quits on worker recruiting behavior at the establishment level using microdata from the Job Openings and Labor Turnover Survey (JOLTS) recently developed by the Bureau of Labor Statistics (BLS). The data are ideal for our purposes because they are a survey of establishments that directly report vacancies, hires and most importantly, separations identified as either quits, layoffs, or other separations. We find evidence that quits may in fact lead to considerable recruitment and hiring. First, quits comprise the majority (54 percent) of separations. Second, establishments with a quit account for a disproportionate share of subsequent hires and vacancies. The make up 58 percent of employment, but account for 65 percent of all hires and 74 percent of all vacan-

cies. Third, we replicate previous research ([9], [6]) in finding a negative relation between quits and establishment-level employment growth and a positive relation between hires and growth. Nevertheless, we find direct, *positive* relationships between the incidence of a quit and subsequent hiring and vacancy posting. These relationships hold after differentiating between expanding, contracting and stable establishments and after controlling for both growth and establishment-specific effects. In short, a disproportionate amount of recruiting activity occurs directly following a quit.

We next formalize our notion of a quit replacement decision within a labor-market search and matching framework. We build upon the standard model of [15] and allow for on-the job search as in [16]. On-the job search, along with the existence of multi-worker firms, are two key features of our model. The key innovation of the model is its differentiation between the cost of advertising a vacancy and the cost of creating a new position. We impose a creation cost similar to that of [11] that is convex in the number of positions created. This feature allows us to distinguish between a hire to replace a quit and a hire for a new position. In the model, unemployed workers randomly contact open positions created by firms whose idiosyncratic productivity, ε, changes over time. An adverse shock to firm productivity can result in an endogenously-determined separation of workers from the firm, if ε falls below some threshold. A favorable shock can result in a firm expansion, which would require the costly creation of new positions and the recruitment of new workers. Within this framework, firms with open positions randomly make contact with employed workers. If a new offer dominates her current job, the worker quits and takes the new job, leaving the original employer with a decision to either replace her (and only incur the cost of advertising the vacancy) or contract through attrition (and lose the sunk cost of the position's capital). The model predicts a rich pattern of job creation and job destruction wherein a firm makes its quit replacement decision. In particular, a firm posts a vacancy to replace a quit only if its productivity is above some endogenously-determined threshold. Otherwise, the job is destroyed and the firm contracts. Finally, firms whose productivity is above an endogenously-determined third threshold open vacancies for new positions in addition to replacing workers.

These dynamics identify a continuum of decision rules that depend on the firm-specific productivity level, where firms go from choosing to contract through layoffs, to choosing to contract through attrition, to remaining stable by replacing their turnover, to expanding through job creation. Through this continuum, the model implies that new vacancy openings increase with firm productivity, quits and layoffs decline with firm productivity, and the probability that a worker accepts a new job offer increases with the productivity of that job, all of which are consistent with our empirical evidence.

After documenting the many qualitative predictions of the model using numerical examples, we test the predictions of the model using a Simulated Method of Moments approach to match the model-generated moments to key features of the data. We simulate our model on a weekly basis and aggregate the simulated data to monthly observations, thereby addressing the issue of time aggregation that is so prevalent in the fast-moving U.S. labor market even with monthly observations.

In addition to the models cited above, our process of on-the-job search and replacement is closely related to the concept of "vacancy chains' described by [1]. It also builds on models that incorporate firm size such as [2] and [3]. Both our theory and evidence are motivated by the establishment-level empirical facts set forth by [6], [7], and [9]. Finally, our model and structural estimation approach is similar to that of [5], though we include on the job search and are more concerned with the cross-section responses of establishments than aggregate implications.

2   Evidence on worker replacement and recruitment

2.1   Data

For our empirical analysis, we use microdata from the Job Openings and Labor Turnover Survey (JOLTS), produced by the BLS. The JOLTS data are a sample of roughly 16,000 establishments. Respondents belong to either a certainty sample or a rotating sample. Those in the latter group are sampled randomly and rotate out after 18 months. The data include

monthly observations on the establishments' employment, hires, separations, and vacancies (job openings). The data are ideal for our purposes because they break out separations into quits, layoffs and discharges, and other separations (e.g., retirements), are reported directly by establishments, and are representative of the U.S. economy. We use data pooled over the December 2000 to January 2005 period and restrict our sample to establishments with observations in at least two consecutive months to avoid issues with establishment entry and exit. Our final sample contains about 372,000 establishment-month observations.

Even with all of its advantages, using the JOLTS data still leaves us with several empirical challenges to address. The first is endogeneity. Theoretically, worker turnover and recruitment are jointly determined by the prospects an establishment faces. We deal with this easily enough in our model. For the empirical analysis, we use the growth rate of the firm as a proxy to differentiate establishments with different prospects. We define this growth rate using the symmetric growth measure of [8] as defined using the JOLTS data by [6]. Growth at establishment i in month t, g_{it} is

$$
g_{it} = \frac{H_{it} - S_{it}}{\frac{1}{2}(N_i t + \widetilde{N}_{i,t-1})} \tag{1}
$$

where H_{it} is the number of hires, S_{it} is the number of separations, N_{it} is employment and $\widetilde{N}_{i,t-1} = N_{it} - H_{it} + S_{it}$. We use the revised measure of employment in $t-1$ based on the JOLTS timing differences described in [9]). Thus, an establishment's growth rate is its net employment change divided by the average of the current and previous months' employment. We measure hiring, quit, layoff, and vacancy rates using the same denominator.

Our next challenge deals with Observability. Ideally, we would like information relating hires and vacancies to quits at the position-level, but our data are at the establishment level. Our model and its estimation again can explicitly account for this. In our empirical analysis, the best we can do is to analyze the establishment-level data with particular attention paid to the frequency and timing of quits, vacancies and hires. This leads us to our next challenge:

timing. JOLTS measures hires and separations flows over the month, and vacancies as a stock at the end of the month. This difference is important to note for our study, since it means that vacancies opened and filled during the month will not appear in our sample, resulting in a time aggregation problem that we address in the simulation of our structural model. [1] It also gives us guidance on the appropriate sequencing of quits, vacancies, and hires for our analysis. Namely, if a worker quits in month t, we will likely observe any related vacancy at the end of month t and a subsequent hire during month $t+1$. This, of course, assumes that the vacancy was not posted and filled the same month the quit occurred. Below, we focus our analysis on the sequencing as described, but also present results relating contemporaneous quits and hires.

Our final challenges deal with the size and fixed characteristics of establishments. By their nature, smaller establishments will have "lumpy' employment changes. Their growth rates are often zero, and conditional on being nonzero they tend to be relatively large in absolute value by construction. In addition, some establishments tend to be high-turnover establishments (perhaps because of their industry, demand structure, labor force composition, etc.) and others do not. Consequently, we report our main results by establishment size class and industry, and where appropriate, we control for the presence of establishment fixed effects.

2.2   Quits, recruitment, and establishment growth

Quits comprise a large fraction of worker turnover, accounting for 54 percent of all separations in the JOLTS data. An important part of understanding the effect of quits on recruitment behavior is understanding how they relate to establishment growth. In relating theory to the evidence, one can think of employment growth (particularly the high-frequency changes we observe in our data) as being determined by idiosyncratic shocks to firm profitability (i.e., productivity or demand), a relationship we make explicit in our structural model. Moreover,

---

[1][4] report that, in the 1982 Employment Opportunity Pilot Project, 44 percent of vacancies ended within 7 days and 72 percent of vacancies ended within two weeks.

matching models with on-the-job search, such as the one we present below, imply that the likelihood that a worker quits decreases with a firm's profitability, since the probability of receiving a more attractive outside offer decreases as the fortune of the current employer improves. At the same time, adverse shocks to profitability increase the likelihood of a layoff and decrease the payoff from opening new vacancies. Thus, the theory suggests rather complex relationships between, worker flows, vacancies, and establishment growth that are intermingled with the quit-recruitment relationship.

[6] and [7] illustrate that these relationships are indeed quite complicated. We replicate their findings in Figures 1 through 3 using our pooled establishment-month observations. [2] Figure 1 shows the quit and layoff rates as functions of the (contemporaneous) establishment employment growth rate. It illustrates that both quits and layoffs increase with the size of an employment contraction, are low and essentially constant in expanding establishments, and are lowest for establishments with very little or no employment change. Among stable and expanding establishments, quits outpace layoffs, while among contracting establishments, layoffs increase sharply and almost linearly with the size of a contraction. Quits, however, increase rapidly with smaller contractions, but then level off at around 10 percent of employment for larger contractions. Thus, quits are relatively more important than layoffs for small contractions, but layoffs account for an increasing share of separations as contractions get larger. When interpreting these figures, note that over 90 percent of employment is at establishments with absolute growth rates less than 10 percent, implying that quits are the dominant separation for most employment changes. Figure 2 depicts hiring and vacancy rates as functions of the contemporaneous establishment growth rate. The figure illustrates a small, but positive amount of hiring among shrinking establishments. Stable establishments have the lowest hiring rate, while the hiring rate increases almost linearly with establishment growth rate for expanding establishments (in some sense, the latter has to occur by construction). Vacancy rates exhibit a similar nonlinear increasing relation to

---

[2]Davis et al. estimate these relationships by calculating the weighted mean values of the noted variables for fine growth rate intervals using the same JOLTS sample as our own. In a semi-parametric estimation, they show these results are robust to the inclusion of establishment fixed effects.

the establishment growth rate, but rise less rapidly than hires. Finally, Figure 3 shows that the vacancy yield (the number of hires in month t per vacancies open at the end of month $t-1$ for establishments reporting at least one vacancy) as a function of the establishment employment growth rate in month t. Due to the timing difference and the requirement of positive reported vacancies, this is not simply a ratio of the two lines in Figure 2. Nonetheless, the vacancy yield is rapidly increasing with the establishment growth rate, particularly among expanding establishments.

2.3 The micro behavior of recruitment and quits

As explained earlier, we are most interested in how the incidence of a quit relates to subsequent establishment recruiting behavior. Consequently, we look next at how quits in one month relate to vacancies posted at the end of the same month and hires made in the subsequent month. Given the timing and Observability issues discussed above, this provides an imperfect measure of the response to a quit. We attempt to address this in our regression analysis below. For now, the results we present here give an informative (and as it turns out, robust) first glance at the issue at hand.

We report basic summary statistics in Table 1. The table shows worker turnover and vacancy rates for the full sample and the sample broken down by whether a quit occurred in the previous month. The quit rate represents 1.7 percent of all employment, and 3.0 percent of employment among establishments with at least one quit. Layoffs and discharges, the other major type of worker separation, represent 1.1 percent of all employment, with a slightly higher rate (1.3 percent) at establishments without a quit. The hiring rate is 3.2 percent of employment, and notably higher at establishments reporting a quit in the previous month, 3.6 versus 2.7 percent. The vacancy rate, which is 2.2 percent for all establishments, is 1.2 percent at establishments with no previously reported quit and more than double that (2.8 percent) at establishments who report at least one quit. The bottom half of Table 1 shows that only 14 percent of all establishments report any quits in the preceding month. These establishments make up nearly 58 percent of employment, implying that most quits occur at

8

larger establishments. These establishments also account for 65 percent of all hires and 74 percent of all vacancies, implying that the incidence of a quit is related to a disproportionate occurrence of vacancies and hiring.

Table 2 illustrates the relation of quit incidence to the discrete events of a vacancy or a hire by the prior incidence of a quit. We report the probability of both based on quit incidence for all establishments, by industry and by establishment size. Given our earlier discussion of establishment size and turnover issues, we have to address the facts that establishments will have fixed characteristics (such as their industry) that affect their rates of turnover and recruitment and that the probability of experiencing at least one quit is strongly influenced by establishment size. For all establishments, our evidence suggests that the incidence of a quit substantially increases the probability of a subsequent vacancy or hire. The likelihood of each increases on the order of 50 percentage points. This pattern holds across industries and size classes, though there is considerable variation in the difference by quit incidence. For example industries such as Government, and Health and Education, industries that [7] show most likely use more-formal hiring practices, have higher probabilities of vacancies and hires independent of quit incidence and a larger difference (in absolute and relative terms) between their probabilities with and without a quit. Across establishment size classes, the probabilities of a vacancy or hire increase with size, and in all cases these probabilities are higher when there is a preceding quit.

Figure 4 depicts the continuous relationships between hires, vacancies and a previously reported quit. It shows the establishment-level hiring rate (upper panel) and vacancy rate (lower panel) as functions of the previous month's quit rate. [3] We disaggregate the relations by expanding, contracting and stable establishments to crudely account for the endogeneity issue discussed above. Hiring and vacancy rates increase with the quit rate. Both relationships, particularly for vacancies, exhibit concavity. Among vacancies, the greatest increase occurs between quit rates of 0.1 and 1.2 percent. The distinction by growth rate has only

---

[3]We estimate these rates as means calculated within fine quit rate intervals that increase with the quit rate. We use the variable interval length because of large drop-off in the number of observations as the quit rate increases.

a quantitative impact on the relationships of hiring and vacancies to the prior month's quit rate. In all cases, the relationships have qualitatively similar increases with quits. As expected, expansions have the highest hiring and vacancy rates. The increase for hires for this group is not tautological, since quits are for the prior month. Note that there is a spike in the hiring and vacancy rates for establishments with no quits, particularly among expanding establishments, indicating that substantial recruiting occurs for this group regardless of quit incidence. Hiring and vacancy rates are lower for contracting and stable establishments, but still increase with the quit rate. The rates and patterns are qualitatively similar for both groups.

2.4   Regression analysis

Thus far, despite measurement challenges related to timing, observability, endogeneity and establishment characteristics, our evidence has consistently suggested a positive relation between the incidence of a quit and subsequent vacancies and hiring. This relation occurs despite the fact that quit rates decline with establishment growth and vacancy and hiring rates increase with establishment growth. For our final analysis, we study the quit-recruitment relation within a regression framework, where we can control for the effects of establishment characteristics and growth.

Table 3 lists the regression results of hires (both in the subsequent and current months, since a quit may be replaced within the same month) and vacancies on the quit rate, controlling for various characteristics. For each dependent variable we run (1) the unconditional OLS regression of the variable on the quit rate, (2), the same regression controlling for establishment fixed effects, (3) the regression controlling for establishment fixed effects and the employment growth rate, and (4) the regression controlling for establishment fixed effects and the growth rate differentiated into positive and negative changes. For the regressions of contemporaneous hires on the quit rate, we face an endogeneity issue when we include the growth rate in the latter two specifications. To account for this, we employ an instrumental variables approach using the prior month's growth rate as the instrument.

To summarize, Table 3 shows that the positive relations of leading hires, contemporaneous hires, and vacancies to quits are robust to controlling for establishment fixed effects and establishment growth. Contemporaneous hires actually have a stronger relation to the quit rate than hires in the subsequent month. These hires can of course occur before a quit, confounding the relation we wish to identify. Nevertheless, even when controlling for and instrumenting for the growth rate, the relationship between these hires and the quit rate still holds.

Finally, we replicate the regressions in columns (1), (2), and (3) substituting the continuous quit rate variable with dummy variables for fine quit rate intervals. [4] We then plot the quit coefficients graphically (with the means added back for the specifications including fixed effects and/or growth). We again use an IV estimate when including the growth rate in the regression of contemporaneous hires. Our results are in Figure 5. Note that the unconditional regression specifications (analogous to column (1) in Table 3) produce estimates identical to those in Figure 4 for the case where hiring and vacancy rates are not differentiated by type of establishment growth. Consequently, we observe the same increasing relationships of hiring and vacancies to quits that we saw in the previous figure. What is important to note, however, is that when we control for establishment fixed effects and establishment growth, the slope of the relationships become flatter (particularly for leading hires), but the positive relations remain in all cases.

To summarize our empirical analysis, we find that establishments with a quit account for a disproportionately large fraction of subsequent vacancies and hiring. Furthermore, across a broad set of metrics, we find a positive relationship between the incidence of a quit and subsequent vacancies and hiring. This relation holds up even after controlling for endogeneity issues related to establishment growth, timing and observability issues that come from studying establishment rather than position-specific data, and fixed establishment characteristics, including industry and size. Thus, it is likely that quits generate a considerable amount of vacancies and hires and that this process accounts for a large fraction of high-frequency

---

[4]These intervals are identical to those used to generate the relations observed in Figure 4.

labor-market dynamics.

3   Model

We next seek to characterize the above findings within a theoretical framework. To do so, we consider a matching model with search frictions and endogenous separations, in the spirit of [15]. We also allow for on-the-job search, as in [18]. Our main innovation, and the features that allow us to identify dynamics related to quits, are the introduction of multi-worker firms and recruiting costs differentiated between a sunk job creation cost and a flow cost of advertising a position (as in [11]) within this framework.

3.1   Model setup

Consider an economy populated by workers and firms who are both risk-neutral and discount future incomes at a rate r. There is a unit measure of workers. Workers have a flow utility of b while unemployed. There is a measure α of firms who each employ one or more workers. A firm's idiosyncratic productivity is ε, which is distributed according to $F(\varepsilon) : [0, \bar{\varepsilon}] \to [0, 1]$. At rate γ_{ε}, each firm draws a new productivity realization from the distribution $F(\cdot)$.

The output of a particular position at a firm with productivity ε is $\varepsilon\nu$, where ν is an indicator variable that determines whether or not the position is productive. All positions are initially productive when created. Subsequently, a new value of the position-specific ν is drawn at rate γ_{ν}, where ν takes on the value of 0 with probability $\frac{\delta(\varepsilon)}{\gamma_{\nu}}$ and the value of 1 with probability $1 - \frac{\delta(\varepsilon)}{\gamma_{\nu}}$, where $\delta(\varepsilon)$ is a decreasing function. Once a position becomes unproductive (because $\nu = 0$), it remains so forever. Workers also leave the firm for exogenous reasons at a rate δ_0, which also renders the position permanently unproductive.

Firms hire workers by either creating or having positions come available then posting vacancies to fill those positions. Vacancies at a firm are filled independently of one another. The upfront cost of creating v positions is equal to $C(v)$, where $C(\cdot)$ is a strictly increasing and strictly convex function with $C(0) = 0$ and $C'(0) \geq 0$. The flow cost of keeping a

vacant position open is c. If a vacant position closed without being filled, the position ceases to exist. If a worker quits the firm or leaves for exogenous reasons, the firm can repost the vacated position at flow cost c. In this case, the firm incurs no fixed cost of position creation, making it less costly to recruit for an existing position than for a newly created position, a crucial feature of the model. If a firm does not search to replace a worker at the time of her departure, the position ceases to exist. The firm can also terminate workers and positions at any time.

Workers can search while unemployed and employed. Given that jobs at different firms vary in their productivity, workers have an incentive to search on-the-job. To keep the model simple, the search intensity of employed workers is fixed at $s \in (0, 1]$, while that of unemployed workers is normalized at 1.

Wages in the model are determined by surplus sharing. The outside option of the firm is the reposting of the vacant position while the outside option of the worker is unemployment. Notice that once a match is created, there is no interaction between the workers in a firm. Hence, the surplus of a match is independent of the number of workers a firm employs. In other words, the concept of a firm embedded in the model is that of a multi-worker entity experiencing a common productivity process.

Contacts between vacancies and searching workers are generated by a matching function with the standard properties, implying that workers contact a firm at rate $\lambda(\theta)$ per unit of search effort, and firms contact workers at rate $\eta(\theta)$, where $\theta = \frac{v}{u+s(1-u)}$ defines labor market tightness in the model.

3.2 Characterization of the stationary equilibrium

Let us next introduce some notation. Let the rate at which workers quit to take another job be $\mu(\varepsilon)$. Let the probability that firm of type ε succeeds in filling a vacant position upon contacting a worker be $\xi(\varepsilon)$. Let the unnormalized distribution of firm productivity across vacancies be $H(\varepsilon)$, so that $H(\bar{\varepsilon}) = v$. Then, denote the normalized distribution of productivity across vacancies by $\hat{H}(\varepsilon) = \frac{H(\varepsilon)}{v}$. Finally, let the unnormalized distribution of

productivity across filled positions be $K(\varepsilon)$, so that $K(\bar{\varepsilon}) = 1 - u$.

Next, we derive the Bellman equations characterizing the value of employment and unemployment for workers and the value of a filled and unfilled position for a firm. Notice that due to the linearity of the production function and the fact that the positions of a firm are filled independently of one another, the only state variable that affects the value of a position, and thereby wages, is firm productivity.

The value of a productive job for a worker is

$$rW(\varepsilon) = w(\varepsilon) + s\lambda(\theta) \int I\left(W(\varepsilon') > W(\varepsilon)\right) \left(W(\varepsilon') - W(\varepsilon)\right) d\hat{H}(\varepsilon') +$$

$$+ \ \gamma_\varepsilon \int \left[\max\left[W(\varepsilon') - U, 0\right] + U - W(\varepsilon)\right] dF(\varepsilon') - \left(\delta(\varepsilon) + \delta_0\right)\left(W(\varepsilon) - U\right), \qquad (2)$$

where U is the value of unemployment for the worker. The first term is the flow wage received by the worker. The second term reflects the gain due to a quit, which takes place if the job offer the worker encounters has a higher value to the worker than its current job. The third term reflects the change in value associated with a new draw of firm productivity. The last term reflects the loss of value associated with the job becoming unproductive or the worker leaving the firm for exogenous reasons. The value of unemployment can be expressed as

$$rU = b + \lambda(\theta) \int \max\left[W(\varepsilon') - U, 0\right] d\hat{H}(\varepsilon'), \qquad (3)$$

where the first term is the flow payoff received by an unemployed worker and the second term reflects the gain from meeting a vacant position.

Similarly, the value of a filled position at a firm with productivity ε is

$$rJ(\varepsilon) = \varepsilon - w(\varepsilon) - s\lambda(\theta) \int I\left(W(\varepsilon') > W(\varepsilon)\right) \left(J(\varepsilon) - R(\varepsilon)\right) d\hat{H}(\varepsilon') + \qquad (4)$$

$$+ \ \gamma_\varepsilon \int \left[\max\left[J(\varepsilon') - R(\varepsilon'), 0\right] + R(\varepsilon') - J(\varepsilon)\right] dF(\varepsilon') - \delta(\varepsilon) J(\varepsilon) - \delta_0\left(J(\varepsilon) - R(\varepsilon)\right),$$

where $R(\varepsilon)$ is the expected value of having a vacant position. Here, the second term reflects the loss of value associated with a worker quit, which occurs as described above. The value

14

of a vacant position is determined by

$$rR(\varepsilon) = \max\left[0, -c + \eta(\theta)\xi(\varepsilon)\left(J(\varepsilon) - R(\varepsilon)\right) + \gamma_\varepsilon \int \left[R(\varepsilon') - R(\varepsilon)\right] dF(\varepsilon') - \delta(\varepsilon) R(\varepsilon)\right]. \quad (5)$$

To ensure that it is never optimal for a firm to keep a vacant position open while that position cannot be profitably operated at current productivity, we make the following assumption:

Assumption 1. *The cost of vacancy posting is large enough so that* $\gamma_\varepsilon \int R(\varepsilon')dF(\varepsilon') \le c$.

To eliminate wages from the above expressions, let us define total match surplus as $S(\varepsilon) = J(\varepsilon) + W(\varepsilon) - R(\varepsilon) - U$. Given surplus sharing, with the worker's share denoted as β, worker surplus will be $W(\varepsilon) - U = \beta S(\varepsilon)$ and firm surplus will be $J(\varepsilon) - R(\varepsilon) = (1-\beta)S(\varepsilon)$. Summing Equations (2) and (4), and using that $I(W(\varepsilon') > W(\varepsilon)) = I(S(\varepsilon') > S(\varepsilon))$ we get that

$$r\left(S(\varepsilon) + R(\varepsilon) + U\right) = \varepsilon + s\lambda(\theta) \int I\left(S(\varepsilon\prime) > S(\varepsilon)\right)\left(\beta S(\varepsilon\prime) - S(\varepsilon)\right) d\hat{H}(\varepsilon\prime) + \quad (6)$$

$$+ \quad \gamma_\varepsilon \int \left[\max\left[S(\varepsilon'), 0\right] + R(\varepsilon') - R(\varepsilon) - S(\varepsilon)\right] dF(\varepsilon') - \delta(\varepsilon)\left[S(\varepsilon) + R(\varepsilon)\right] - \delta_0 S(\varepsilon).$$

Using the definition of the surplus function, we can rewrite the asset equation for the value of a vacant position as

$$(r + \gamma_\varepsilon + \delta(\varepsilon)) R(\varepsilon) = \max\left[0, -c + \eta(\theta)\xi(\varepsilon)(1 - \beta)S(\varepsilon) + \gamma_\varepsilon \int R(\varepsilon')dF(\varepsilon')\right]. \quad (7)$$

Clearly, the functional equations for $S(\cdot)$ and $R(\cdot)$ jointly define a contraction which maps increasing functions into increasing functions, hence the Contraction Mapping Theorem implies that $S(\cdot)$ and $R(\cdot)$ are increasing, hence $W(\cdot)$ is also increasing.

Given monotonicity, workers will accept all jobs that have a firm productivity higher than that of their current firm. Thus,

$$\mu(\varepsilon) = s\lambda(\theta)\left(1 - \hat{H}(\varepsilon)\right), \quad (8)$$

and

$$\xi(\varepsilon) = \frac{u + s(1-u)\frac{K(\varepsilon)}{K(\tilde{\varepsilon})}}{u + s(1-u)} = \frac{u + sK(\varepsilon)}{u + s(1-u)}, \tag{9}$$

while the surplus function can be written as

$$rS(\varepsilon) = \varepsilon - rU + s\lambda(\theta)\int_{\varepsilon}\beta S(\varepsilon')d\hat{H}(\varepsilon') - (\mu(\varepsilon) + \delta(\varepsilon) + \delta_0)S(\varepsilon) + \tag{10}$$

$$+ \quad \gamma_\varepsilon \int \left[\max\left[S(\varepsilon'),0\right] + R(\varepsilon') - R(\varepsilon) - S(\varepsilon)\right]dF(\varepsilon') - [r + \delta(\varepsilon)]R(\varepsilon).$$

Let $\tilde{\varepsilon}$ be where $S(\tilde{\varepsilon}) = 0$. Notice that a firm will close all the positions it operates once ε falls below $\tilde{\varepsilon}$. We will maintain that $\tilde{\varepsilon} > 0$, to induce sufficiently unproductive firms to shut down.

Given Assumption 1, $R(\tilde{\varepsilon}) = 0$, and using that $S(\tilde{\varepsilon}) = 0$, we get, after substituting in for the value of unemployment, that $\tilde{\varepsilon}$ is implicitly defined by

$$b = \tilde{\varepsilon} - (1-s)\lambda(\theta)\int_{\tilde{\varepsilon}}\beta S(\varepsilon')d\hat{H}(\varepsilon') + \gamma_\varepsilon\int\left[\max\left[S(\varepsilon'),0\right] + R(\varepsilon')\right]dF(\varepsilon'). \tag{11}$$

The difference between b and $\tilde{\varepsilon}$ comes from two sources: the higher option value of search while unemployed (due to higher search intensity while unemployed), reflected by the second term on the right-hand side, and the option value of changing productivity, reflected by the third term on the right-hand side.

Next, let the lowest productivity for which it is worthwhile to repost a vacancy be $\hat{\varepsilon} \geq \tilde{\varepsilon}$. Note that the fixed cost of creating a new position implies that $R(\varepsilon)$ will not go to zero for firms with $\varepsilon > \hat{\varepsilon}$, even with free entry. Firms with productivity $\varepsilon \in (\tilde{\varepsilon}, \hat{\varepsilon})$ find it profitable to continue existing relationships, but they do not find it profitable to replace lost workers due to separations into unemployment (at rate $\delta(\varepsilon) + \delta_0$) or due to quits (at rate $\mu(\varepsilon)$). Therefore, while these firms do not shut down, they will contract by attrition. Clearly, $R(\hat{\varepsilon}) = 0$, and for any $\varepsilon > \hat{\varepsilon}$, $R(\varepsilon) > 0$, indicating a positive return to posting a vacancy, so $\hat{\varepsilon}$ is implicitly

defined by

$$c = \eta(\theta)\xi(\hat{\varepsilon})(1-\beta)S(\hat{\varepsilon}) + \gamma_\varepsilon \int R(\varepsilon')dF(\varepsilon'). \tag{12}$$

Given the upfront cost of creating new positions, a firm with productivity ε opens $v(\varepsilon)$ new positions where

$$C'(v(\varepsilon)) \geq R(\varepsilon) \tag{13}$$

. With complementary slackness, $v(\varepsilon) \geq 0$. Given the assumption that $C'(0) \geq 0$, new positions will be created by firms with productivity above $\check{\varepsilon} \geq \hat{\varepsilon}$, where

$$C'(0) = R(\check{\varepsilon}). \tag{14}$$

Moreover, given the properties of $C(\cdot)$ and $R(\cdot)$, $v(\cdot)$ is increasing in ε. Thus, $\check{\varepsilon}$ defines a third productivity threshold. Firms with productivity $\varepsilon \in (\hat{\varepsilon}, \check{\varepsilon})$ find it profitable to replace workers who have left, but do not find it profitable to open new positions because of their upfront cost. Such firms will be either stable (if $\delta(\varepsilon) = 0$) or shrinking over time (if $\delta(\varepsilon) > 0$), since they still face the exogenous loss of unproductive positions. Firms with productivity above $\check{\varepsilon}$ not only replace lost workers, but also expand by creating new positions.

Finally, one can derive the distribution of productivity across vacancies and jobs in a stationary equilibrium from the appropriate balance equations. In particular, equating the flow into $H(\varepsilon)$ (made up of new vacancies, reposted vacancies, and vacancies that had a change in their productivity) and the flow out of $H(\varepsilon)$ (made up closed, unfilled vacancies, filled vacancies, and vacancies that had a change in their productivity) gives

$$\alpha \int_{\hat{\varepsilon}}^{\varepsilon} v(\varepsilon')dF(\varepsilon') + \int_{\hat{\varepsilon}}^{\varepsilon} (\mu(\varepsilon') + \delta_0) \, dK(\varepsilon') \quad + \quad \gamma_\varepsilon H(\bar{\varepsilon})\left[F(\varepsilon) - F(\hat{\varepsilon})\right] = \tag{15}$$

$$= \int_{\hat{\varepsilon}}^{\varepsilon} \left[\delta(\varepsilon') + \eta(\theta)\xi(\varepsilon')\right] dH(\varepsilon') + \gamma_\varepsilon H(\varepsilon).$$

Similarly, equating the flow into $K(\varepsilon)$ (made up of filled vacancies and jobs that had a change in their productivity) and the flow out of $K(\varepsilon)$ (made up destroyed jobs, jobs that become vacant due to a quit or exogenous separation, and jobs that had a change in their productivity) gives

$$\int_{\tilde{\varepsilon}}^{\varepsilon} \eta(\theta)\xi(\varepsilon')dH(\varepsilon') + \gamma_{\varepsilon}K(\overline{\varepsilon})\left[F(\varepsilon) - F(\tilde{\varepsilon})\right] = \int_{\tilde{\varepsilon}}^{\varepsilon} \left(\delta(\varepsilon') + \mu(\varepsilon') + \delta_0\right)dK(\varepsilon') + \gamma_{\varepsilon}K(\varepsilon).$$

(16)

3.3 Solving for the stationary equilibrium

To solve for the equilibrium objects $S(\varepsilon)$, $R(\varepsilon)$, $H(\varepsilon)$, and $K(\varepsilon)$, it is useful to derive differential equations characterizing these functions together with the appropriate boundary conditions.

Differentiating Equation (7) with respect to ε gives for $\varepsilon \in [\hat{\varepsilon}, \overline{\varepsilon}]$

$$R'(\varepsilon)\left(r + \gamma_{\varepsilon} + \delta(\varepsilon)\right) + R(\varepsilon)\delta'(\varepsilon) = (1-\beta)\eta(\theta)\left[\xi'(\varepsilon)S(\varepsilon) + \xi(\varepsilon)S'(\varepsilon)\right].$$

(17)

Differentiating Equation (10) with respect to ε, using $\mu'(\varepsilon) = -s\lambda(\theta)\hat{h}(\varepsilon)$, then substituting in from Equation (17) for $\varepsilon \in [\hat{\varepsilon}, \overline{\varepsilon}]$ and recognizing that $R(\varepsilon) = 0$ for $\varepsilon \in [\tilde{\varepsilon}, \hat{\varepsilon})$, gives for $\varepsilon \in [\tilde{\varepsilon}, \overline{\varepsilon}]$

$$(r + \delta(\varepsilon) + \mu(\varepsilon) \quad + \quad \delta_0 + \gamma_{\varepsilon} + I\left(\varepsilon \geq \hat{\varepsilon}\right)(1-\beta)\eta(\theta)\xi(\varepsilon))\,S'(\varepsilon) = \tag{18}$$
$$= \quad 1 + \left[(1-\beta)\left(s\lambda(\theta)\hat{h}(\varepsilon) - I\left(\varepsilon \geq \hat{\varepsilon}\right)\eta(\theta)\xi'(\varepsilon)\right) - \delta'(\varepsilon)\right]S(\varepsilon).$$

Differentiating Equation (15) with respect to ε for $\varepsilon \in [\hat{\varepsilon}, \overline{\varepsilon}]$ and differentiating Equation (16) with respect to ε for $\varepsilon \in [\tilde{\varepsilon}, \overline{\varepsilon}]$ and combining these results give for $\varepsilon \in [\tilde{\varepsilon}, \hat{\varepsilon})$

$$k(\varepsilon) = \frac{\gamma_{\varepsilon}\left(1 - u\right)f(\varepsilon)}{\delta(\varepsilon) + \mu(\varepsilon) + \delta_0 + \gamma_{\varepsilon}}$$

(19)

and for $\varepsilon \in [\hat{\varepsilon}, \overline{\varepsilon}]$

$$h\left(\varepsilon\right) = \frac{\alpha v(\varepsilon) + \left(\mu(\varepsilon) + \delta_0\right)\frac{\alpha v(\varepsilon) + \gamma_\varepsilon (v+1-u)}{\delta(\varepsilon) + \gamma_\varepsilon} + \gamma_\varepsilon v}{\delta\left(\varepsilon\right) + \eta(\theta)\xi(\varepsilon) + \gamma_\varepsilon + \mu\left(\varepsilon\right) + \delta_0} f(\varepsilon) \tag{20}$$

and

$$k(\varepsilon) = \frac{\alpha v(\varepsilon) + \gamma_\varepsilon\left(v + 1 - u\right)}{\delta\left(\varepsilon\right) + \gamma_\varepsilon} f(\varepsilon) - h(\varepsilon). \tag{21}$$

Then one can solve for the stationary equilibrium objects $S(\varepsilon)$, $R(\varepsilon)$, $H(\varepsilon)$, $K(\varepsilon)$, $\mu(\varepsilon)$, $\xi(\varepsilon)$, $v(\varepsilon)$, $\tilde{\varepsilon}$, $\hat{\varepsilon}$, $\check{\varepsilon}$ from Equation (18) together with boundary condition $S\left(\tilde{\varepsilon}\right) = 0$, Equation (17) together with boundary condition $R\left(\hat{\varepsilon}\right) = 0$, Equation (20) together with boundary condition $H\left(\hat{\varepsilon}\right) = 0$, equations (19) and (21) together with boundary condition $K\left(\tilde{\varepsilon}\right) = 0$, and equations (8), (9), (13), (11), (12), and (14). These solutions then determine $u = 1 - K\left(\overline{\varepsilon}\right)$, $v = H\left(\overline{\varepsilon}\right)$, and $\theta = \frac{v}{u+s(1-u)}$.

4   Model implications

Our model has a rich set of implications that we highlight in our simulated estimation below. Here, we detail the implications qualitatively. First, firms with different productivities have different growth patterns and correspondingly have different relationships between quits and vacancy postings. In particular, we can distinguish four regions of productivity depicted in Figure 6. In Region 1, productivity has fallen below the separation threshold and the firm shuts down, destroying all of its jobs. In Region 2, firms are between the separation threshold and the replacement threshold. These firms do not post vacancies, and thereby contract their employment through attrition. In Region 3, firms are between the replacement threshold and the job creation threshold. These firms post vacancies to replace workers who have left, but do not create additional jobs. Finally, firms in Region 4 are above the job creation threshold and therefore have the highest productivity levels and recruit to both replace workers who have left and hire for new positions. Of course, firms move across these

19

regions due to productivity shocks, giving rise to rich employment dynamics.

Figure 7 depicts the key labor variables of the model as a function of ε, with the four regions highlighted. We assume a $\delta(\varepsilon)$ function depicted in panel (a) that turns zero at some intermediate point in Region 3. While this may seem at odds with our empirical evidence, remember that all firms experience exogenous separations at a rate δ_0. The second panel shows that the employment growth rate ($g(\varepsilon)$), independent of idiosyncratic shocks, is an increasing function of firm productivity. Growth in Regions 1 and 2 is negative. Region 3 contains both declining and stable firms; the former exist because a fraction $\delta_0 + \delta(\varepsilon)$ of positions are lost and not replaced. Growth is positive in Region 4 since these establishments expand by posting more vacancies and having a higher success rate in filling them. The next panel shows the rate at which new positions are created. This is an increasing function of ε, but only above $\check{\varepsilon}$, the job creation threshold. The third panel depicts the quit rate, which is a decreasing function of firm productivity. Finally, the probability of filling a vacancy increases with firm productivity for all ε above $\hat{\varepsilon}$. This stems from the fact that firms with higher productivity are able offer higher wages and therefore increase the chance an individual accepts their offer.

Putting these results together, we can see that, qualitatively, these results are consistent with the evidence of [6] and [7] that we depicted in Figures 1-3. For large contractions, layoffs dominate quits, though both are relatively large in magnitude. For smaller contractions, quits are relatively more prevalent than layoffs. The model suggests that this stems from a conscious decision by the firm to contract through attrition. Stable establishments have mix of quits, layoffs, and hiring, albeit at relatively low rates. The model implies that these are the result of hiring to replace lost workers. Expanding establishments have increasing rates of hires and vacancies, and an increasing vacancy yield. The model suggests these patterns stem from relatively high levels of firm productivity, which induce not only more job creation, but also a higher probability of acceptance of these offers.

5   Structural estimation

Given the complexity of the above model, its direct structural estimation is quite cumbersome. To get an idea of how well the model fits the data, we instead take a semi-structural approach. This approach uses the key predictions and boundary conditions of the structural model to define an estimation environment. Rather than deriving the policy functions $\mu(\varepsilon)$, $\delta(\varepsilon)$, $\xi(\varepsilon)$, and $v(\varepsilon)$ directly from the structural model given some deep parameters, we posit that they take functional forms that satisfy the model's monotonicity requirements and boundary conditions.

We then estimate the semi-structural parameters that consist of $\tilde{\varepsilon}$, $\hat{\varepsilon}$, $\check{\varepsilon}$, γ_{ε}, δ_0, η and the parameters that characterize the above policy functions. We use a Simulated Method of Moments (SMM) approach that simulates the growth, recruiting and turnover data for finite-sized firms using the semi-structural parameters. We then choose the optimal parameters estimates so that they minimize the distance between the actual moments and those predicted by the simulated data. (For a detailed discussion of the SMM procedure, see [13].)

5.1   Estimation environment

We set up our estimation environment based on the key predictions and boundary conditions implied by our structural model. Throughout, we take u, v, and θ as given, so our estimation approach can be thought of as characterizing a stationary equilibrium for a given level of labor market tightness. Given that our focus is on the cross-sectional variation in establishment-level turnover and recruiting behavior, we feel this is a valid characterization of the model. Consequently denote $\eta(\theta) \equiv \eta$ throughout this section.

The relevant state variable for a firm is $\varepsilon \in [0, \bar{\varepsilon}]$, which determines the productivity of the matches a firm creates. It is governed by a Poisson process with arrival rate γ_{ε} and distribution upon arrival of $F(\varepsilon)$. We assume throughout that $F(\cdot)$ is uniform over the interval $[0, 1]$. Below some threshold, $\tilde{\varepsilon}$, the firm shuts down and destroys all of its current

positions. Above this threshold, the quit rate is a decreasing function $\mu(\varepsilon)$. This function has the property that $\mu(\bar{\varepsilon}) = 0$ and is characterized in the structural model by Equation (8). Given these properties, we let our estimated function for $\mu(\varepsilon)$ take the form

$$\mu(\varepsilon) = \mu_1 \cdot \eta \left(\frac{\bar{\varepsilon} - \max[\varepsilon, \hat{\varepsilon}]}{\bar{\varepsilon} - \hat{\varepsilon}} \right) \tag{22}$$

for $\varepsilon \geq \tilde{\varepsilon}$, with $\mu_1 > 0$ as one of our estimated parameters. Note that with constant returns in the matching function, $\lambda(\theta) = \theta \eta(\theta)$.

The separation rate at firms is determined by $\delta(\varepsilon)$. This function is exogenous to the model but has the properties that it is decreasing in ε and approaches zero somewhere in the range of $\varepsilon \in [\hat{\varepsilon}, \check{\varepsilon}]$. For simplicity, we characterize the function as

$$\delta(\varepsilon) = (1 - \delta_0) \cdot \exp\left[\delta_1 \left(\varepsilon - \tilde{\varepsilon}\right)\right] \tag{23}$$

for $\varepsilon \geq \tilde{\varepsilon}$, with δ_0 the exogenous, constant separation rate defined in the model, and $\delta_1 < 0$ the parameter that characterizes $\delta(\varepsilon)$.

Searching firms contact workers at a rate η. The rate at which their job offers are accepted is given by an increasing positive function $\xi(\varepsilon)$ such that $\xi(\bar{\varepsilon}) = 1$.With Equation (9), the structural model again gives us some guidance on the form of $\xi(\varepsilon)$. As such, we define $\xi(\varepsilon)$ as a linear function

$$\xi(\varepsilon) = \xi_0 + \xi_1 \left(\varepsilon - \tilde{\varepsilon}\right) \tag{24}$$

for $\varepsilon \geq \hat{\varepsilon}$, the lowest value of e for which a firm will post vacancies. Again, $\xi_0, \xi_1 > 0$ are parameters for our semi-structural estimation.

The number of new positions created by a firm are defined by the increasing function $v(\varepsilon)$, for which $v(\check{\varepsilon}) = 0$. We keep its formulation simple, yet flexible within the characteri-

zation implied by the model with

$$v(\varepsilon) = v_0 \left\{ \exp \left[v_1 \left(\varepsilon - \check{\varepsilon} \right) \right] - 1 \right\} \tag{25}$$

for $\varepsilon \geq \check{\varepsilon}$ and with $v_0, v_1 > 0$ the semi-structural parameters we estimate.

Finally, firms post no vacancies when $\varepsilon \in [\check{\varepsilon}, \hat{\varepsilon}]$, and instead contract at a rate of $\delta_0 + \delta(\varepsilon) + \mu(\varepsilon)$. Firms try to replace quitting workers by posting vacancies when $\varepsilon \geq \hat{\varepsilon}$. Firms try to replace workers and fill $v(\varepsilon)$ newly-created positions when $\varepsilon \geq \check{\varepsilon}$. Whether the vacancy is for a new position or for a replacement, the probability of a hire is $\xi(\varepsilon)\eta$. Overall, this characterization of the structural model leaves us with 12 parameters to estimate: the six implied directly from the model ($\tilde{\varepsilon}$, $\hat{\varepsilon}$, $\check{\varepsilon}$, γ_ε, δ_0, and η) and the six that define $\mu(\varepsilon)$, $\delta(\varepsilon)$, $\xi(\varepsilon)$, and $v(\varepsilon)$.

5.2 Simulation and optimization

We estimate the model parameters using a Simulated Method of Moments approach that matches the moments calculated from simulated data to those obtained directly from the JOLTS data as closely as possible. We simulate the growth, recruiting and turnover dynamics for 5,000 establishments, each observed over 20 months, giving us 100,000 simulated observations to work with. The simulation proceeds as follows. First, we draw an establishment of random size from a lognormal distribution that is scaled to match the mean and variance of the JOLTS establishment size distribution (the mean and variance are listed in Table 4). Next, we assign the establishment a random productivity draw from $F(\varepsilon)$. Finally, we observe the establishment's behavior for 20 periods (which correspond to months in the data). At the beginning of each period, the establishment gets a new draw of ε with probability γ_ε.

To allow our model to deal with some of the data's time aggregation issues noted earlier, we split each period into four "weeks". In doing so, we allow for vacancies to be posted and filled within each period, and are able to keep track of both the vacancy yield and the

23

end-of-month stock of vacancies that is consistent with their JOLTS measurement. To allow for the discrete nature of employment changes, which we noted was an issue particularly for smaller establishments, we round all vacancies and employment flows to integer amounts after calculating the outcomes based on the relevant continuous probability densities. To ensure that no large estimated outliers distort our results, we restrict the simulated sample to establishments with 30,000 workers or less. In the data, this represents all but a few very large establishments.

After simulating our data, we use our observations to calculate the estimated versions of the 40 moments obtain from the JOLTS data. These moments, listed in Table 4 (with the estimated moments above and their values from the data in parentheses), include the means of key employment variables that should be most responsive an establishment's idiosyncratic productivity. We estimate separate moments for contracting, stable, and expanding establishments, based on their contemporaneous growth rate. The first 19 moments include the mean growth rate (g), quit rate (q), layoff rate (l), hiring rate (h), vacancy rate (v), and vacancy yield (y, as defined in the empirical analysis), as well as the employment share for each growth category. The next three moments are the fraction of employment at establishments with at least one quit in each category. The final 18 moments are the mean hiring rate, vacancy rate and vacancy yield by both growth category and quit incidence (i.e., whether or not one occurred that period).

To estimate the model, we seek to choose the set of parameter estimates that minimize the sum of squared differences (normalized by their empirical value) between the simulated and empirical moments. Letting Φ denote our vector of 12 parameters and M denote our vector of 40 moments, our problem is

$$\min_{\{\Phi\}} \left(\frac{M(\Phi) - M}{M} \right) W \left(\frac{M(\Phi) - M}{M} \right)'$$

where W is a weighting matrix that consists of the inverse of the variance of each moment as its diagonal elements. As it turns out, the over-identification of the model and the highly

24

nonlinear relations it tries to estimate lead standard search algorithms to converge to one of many local minima. To overcome this problem, we employ a simulated annealing approach, that randomly checks within a specified distance to see if the minimum achieved is a local or global minimum (see [12] for a detailed description of the simulated annealing approach to optimization). The approach proves ideal for our situation.

5.3 Estimation results

TO BE COMPLETED.

6 Conclusions

In this paper, we have presented evidence that quits are an important part of labor market dynamics. This is especially true of the high-frequency (i.e., monthly) dynamics we observe in the JOLTS data. More than half of all separations are quits, and establishments with at least one quit account for a disproportionate amount of vacancies and hiring. This suggests that quits may drive a large fraction of worker recruitment. In studying the JOLTS microdata both nonparametrically and through regression analysis, we find evidence suggesting that this is indeed the case. Both hires and vacancies are positively related to the incidence of a preceding quit even after controlling for establishment growth and establishment-specific characteristics.

We then develop a matching model that accounts for the empirical patterns we observe. The model builds upon similar matching models with endogenous job destruction and on-the-job search by differentiating between the sunk cost of creating a new position and the flow cost of advertising for a position opening. In the model, multi-worker firms face the standard decision of whether to continue or sever a match after an adverse shock to their productivity. Given the sunk cost of position creation, and on-the-job search, firms face additional decisions related to whether to replace a worker who leaves the firm, and whether to expand employment. This creates three thresholds of firm productivity that define the

25

firm's separation decision, worker replacement decision, and position creation decision. The resulting decision rules create rich employment dynamics where quits and layoffs decrease with firm productivity, vacancies and hiring increase with productivity, and complex interactions between these processes emerge when firms must decide whether to replace a worker who leaves or let a position vanish. Overall, the model produces implications that are generally consistent with our evidence and provides a flexible framework to explore both the micro-level dynamics and the cyclical volatility of employment adjustments in future research.

**Figure 1. Quit and Layoff Rates as a Function of Establishment Growth**
Notes: Figure depicts the quit and layoff rates as functions of the establishment-level employment growth rate (all depicted as fractions of employment), and is taken from Davis, Faberman, and Haltiwanger (2006a, p. 17). Rates are estimated over fine growth rate intervals that increase in size with the magnitude of growth. Estimates use pooled observations of JOLTS microdata, and the figure illustrates rates as a 5-interval centered moving average with a discontinuity allowed at zero-growth.

Figure 2. Hiring and Vacancy Rates as a Function of Establishment Growth
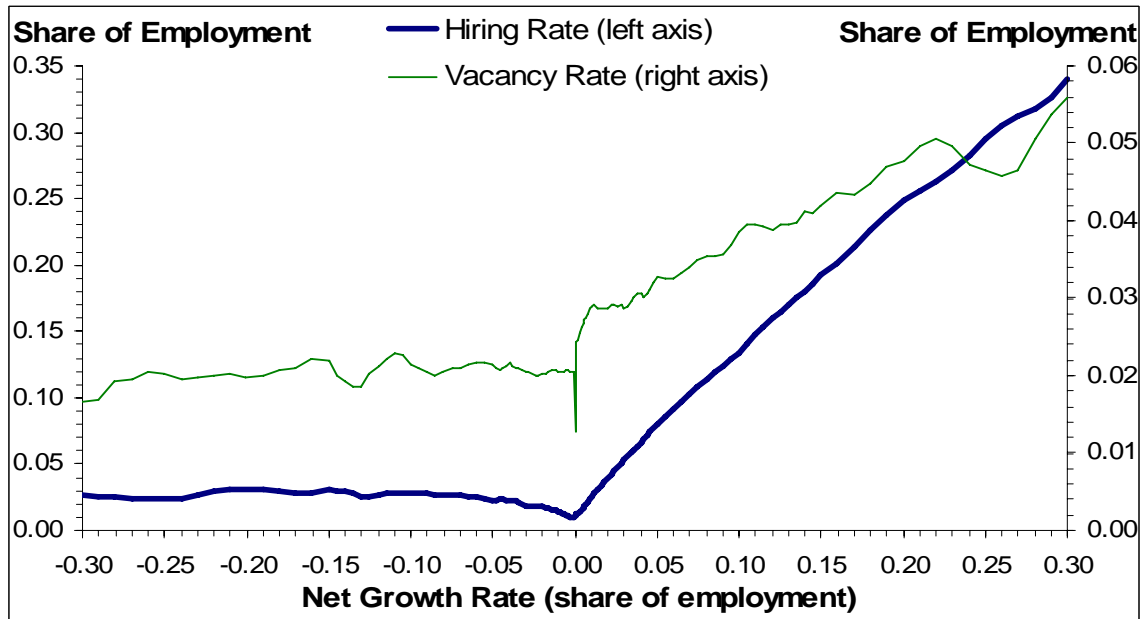

Notes: Figure depicts the hiring and vacancy rates as functions of the establishment-level employment growth rate (all depicted as fractions of employment). Rates are estimated over fine growth rate intervals that increase in size with the magnitude of growth. The figure illustrates rates as a 5-interval centered moving average with a discontinuity allowed at zero-growth. Estimates are from Davis, Faberman, and Haltiwanger (2006b) who use pooled observations of JOLTS microdata.

Figure 3. The Vacancy Yield as a Function of Establishment Growth
Notes: Figure depicts the vacancy yield (measured as hires per reported vacancy for establishments with at least one vacancy) as a function of the establishment-level employment growth rate. The yield is estimated over fine growth rate intervals that increase in size with the magnitude of growth. The figure illustrates rates as a 5-interval centered moving average with a discontinuity allowed at zero-growth. Estimates are from Davis, Faberman, and Haltiwanger (2006b) who use pooled observations of JOLTS microdata.

Figure 4. Hiring and Vacancy Rates vs. the Quit Rate, by Type of Establishment Growth

(a) Leading Hires vs. Quits
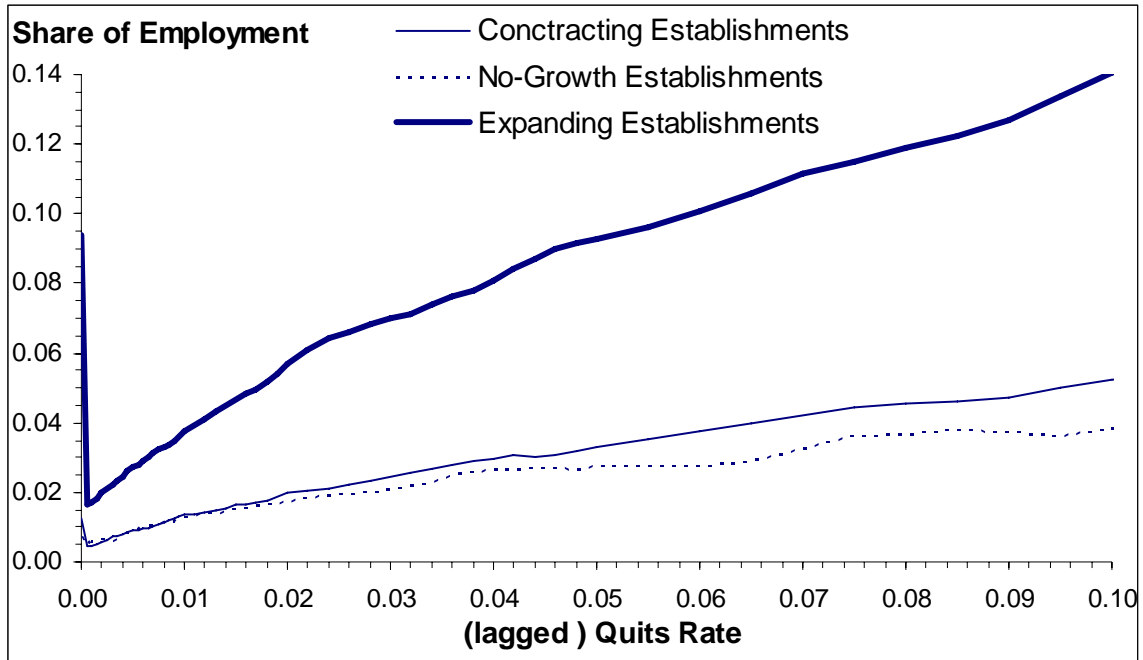

(b) Vacancies vs. Quits
Notes: Figures depict the hires rate (top panel) and vacancy rate (bottom panel) as a function of the establishment-level quit rate (all depicted as fractions of employment) and broken out by type of establishment-level employment growth (expanding, contracting, no change). Rates are estimated over fine quit rate intervals that increase in size with the rate. Estimates are from authors' tabulations using pooled observations of JOLTS microdata, and the figure illustrates rates as a 5-interval centered moving average.

Figure 5. Hiring and Vacancy Rates vs. the Quit Rate, Regression Results

(c) Establishment Size

	$\Pr(v_t > 0)$		$\Pr(h_{t+1} > 0)$		$\Pr(h_{t+1} > 0 \mid v_t > 0)$	
	$q_t = 0$	$q_t > 0$	$q_t = 0$	$q_t > 0$	$q_t = 0$	$q_t > 0$
0-9 Employees	0.06	0.29	0.10	0.36	0.33	0.45
10-49 Employees	0.18	0.42	0.31	0.60	0.52	0.69
50-249 Employees	0.38	0.65	0.54	0.82	0.69	0.87
250-999 Employees	0.60	0.84	0.70	0.90	0.80	0.93
1000-4999 Employees	0.70	0.93	0.81	0.96	0.87	0.98
5000+ Employees	0.81	0.93	0.93	0.99	0.94	0.99

Notes: Estimates are the (employment-weighted) probabilities of a vacancy, hire, or hire conditional on a vacancy based on the incidence of at least one quit. Estimates come from authors' tabulations using pooled observations of JOLTS microdata.

Table 3. Establishment-Level Regressions, Hiring, Vacancies and the Quit Rate

(a) Dependent Variable: $h_{i,t+1}$ (Leading Hires)

	(1)	(2)	(3)	(4)
q_{it}	.222	.050	.069	.056
	[.002]	[.002]	[.002]	[.001]
g_{it}			.012	
			[.001]	
$g_{it} > 0$				.024
				[.001]
$g_{it} < 0$				.003
				[.001]
Establishment Effects?	No	Yes	Yes	Yes
R-squared	.033	.291	.291	.292

(b) Dependent Variable: h_{it} (Contemporaneous Hires)

	(1) OLS	(2) OLS	(3) IV	(4) IV
q_{it}	.592	.347	.153	.665
	[.003]	[.003]	[.090]	[.032]
g_{it}			-.307	
			[.141]	
$g_{it} > 0$				1.170
				[.061]
$g_{it} < 0$				.382
				[.062]
Establishment Effects?	No	Yes	Yes	Yes
R-squared	.120	.319	.319	.320

(c) Dependent Variable: v_{it}

	(1)	(2)	(4)	(5)
q_{it}	.103	.062	.089	.092
	[.001]	[.001]	[.001]	[.001]
g_{it}			.017	
			[.0004]	
$g_{it} > 0$				.015
				[.001]
$g_{it} < 0$				.019
				[.001]
Establishment Effects?	No	Yes	Yes	Yes
R-squared	.022	.410	.413	.413

Notes: Tables report coefficients and standard errors (in brackets) of OLS (or instrumental variables, where noted) for regressions of the noted dependent variable on the noted regressors using pooled establishment-month observations. *N = 371,997*. Regressions include establishment fixed effects where noted. For IV estimates, regressions use the lagged growth rate (or lagged growth rates conditional on being positive or negative) as the instrument(s).

Table 4. Estimated and Actual Moments, Semi-Structural Model Estimation

Establishment Size Distribution			
Mean Employment	20.10	Variance	157.9

Moments based on Establishment Growth			
	Contracting Establishments	**Stable Establishments**	**Expanding Establishments**
Employment Share	(0.315)	(0.321)	x[1] (0.364)
Mean g	(-0.0506)	[0.0000][2]	(0.0390)
Mean q	(0.0310)	(0.0077)	(0.0138)
Mean l	(0.0316)	(0.0035)	(0.0071)
Mean h	(0.0175)	(0.0112)	(0.0634)
Mean v	(0.0257)	(0.0135)	(0.0313)
Mean y	(1.314)	(0.656)	(3.321)

Moments based on Quit Incidence			
Employment Share with $q > 0$	(0.839)	(0.175)	(0.702)
Mean $h \mid q = 0$	(0.0093)	(0.0029)	(0.0805)
Mean $v \mid q = 0$	(0.0162)	(0.0105)	(0.0232)
Mean $y \mid q = 0$	(0.605)	(0.132)	(2.012)
Mean $h \mid q > 0$	(0.0191)	(0.0505)	(0.0562)
Mean $v \mid q > 0$	(0.0275)	(0.0277)	(0.0348)
Mean $y \mid q > 0$	(1.384)	(1.339)	(3.664)

Notes: The table lists the moment estimates from the semi-structural estimation of the model. The estimates of each moment from the data are in parentheses. These estimates use pooled monthly observations of JOLTS establishments ($N = 371{,}858$).
1. Moment calculated as one minus the sum of the estimates of the other two employment shares.
2. Mean growth rate equals zero by definition.
