Growth-Rate and Uncertainty Shocks in Consumption: Cross-Country Evidence

Abstract

We quantify the importance of long-run risks—persistent shocks to growth rates and uncertainty—in a panel of long-term aggregate consumption data for developed countries. We identify sizable and highly persistent world growth-rate shocks as well as less persistent country-specific growth rate shocks. The world growth-rate shocks capture the productivity speed-up and slowdown many countries experienced in the second half of the 20th century. We also identify large and persistent common shocks to uncertainty. Our world uncertainty process captures the large but uneven rise and fall of volatility that occurred over the course of the 20th century. We find that negative shocks to growth rates are correlated with shocks that increase uncertainty. Our estimates based on macroeconomic data alone line up well with earlier calibrations of the long-run risks model designed to match asset pricing data. We document how these dynamics, combined with Epstein-Zin-Weil preferences, help explain a number of asset pricing puzzles.

Keywords: Long-run risks, Uncertainty shocks, Equity premium puzzle.

JEL Classification: E21, G12

1 Introduction

A large recent literature has emphasized the importance of long-run risks—persistent shocks to
growth rates and uncertainty—for explaining a variety of asset market phenomena. Bansal and
Yaron (2004) demonstrated the importance of these features for explaining the high equity premium,
high volatility of stock returns, low and stable risk-free rate and predictability of stock returns.
Subsequent work has used these shocks to explain failures of the expectations hypothesis of the term
structure and uncovered interest rate parity, the return premium on value stocks and small stocks,
the term structure of equity returns, and the volatility of the real exchange rate.\footnote{Important papers include Bansal and Shaliastovich (2010), Bansal, Dittmar, and Lundblad (2005), Hansen,
Heaton, and Li (2008), Malloy, Moskowitz, and Vissing-Jorgensen (2009), Croce, Lettau, and Ludvigson (2010), and
Colacito and Croce (2011). See Bansal, Kiku, and Yaron (2012) for a more comprehensive review of this literature.}
A comparably large recent literature has focused on the macroeconomic consequences of these same types of shocks—
that news shocks about future growth rates are an important driver of business cycles.\footnote{See also Aguiar and Gopinath (2007),
Jaimovich and Rebelo (2009), Barsky and Sims (2010), and Schmitt-Grohe and Uribe (2010).}

Bansal and Yaron (2004) propose the following time-series model of consumption growth:

\[
\begin{align*}
\Delta c_{t+1} &= \mu + x_t + \chi \sigma_t \epsilon_{t+1}, \\
x_{t+1} &= \rho x_t + \sigma_t \epsilon_{t+1}, \\
\sigma^2_{t+1} &= \sigma^2 + \gamma(\sigma^2_t - \sigma^2) + \sigma \omega \omega_{t+1}.
\end{align*}
\]  

(1)

Relative to a simple, random-walk model for consumption, this model adds two novel features: 1) consumption growth is affected by a persistent process \(x_t\), 2) the uncertainty about consumption
growth varies over time in a persistent manner. A difficulty with empirically evaluating this model is
that certain key parameters—e.g., the persistence of \(x_t\) and \(\sigma^2_t\) and the volatility of the innovations
to \(\sigma^2_t\)—are difficult to estimate with 80 years of consumption data from a single country. This has led
authors in the asset pricing literature to focus on calibrations of the long-run risks model designed
to match asset pricing data (Bansal and Yaron, 2004; Bansal et al., 2012).\footnote{Several papers have also used a combination of macroeconomic and asset pricing data to estimate the parameters
of the long-run risks model (e.g., Bansal, Kiku, and Yaron, 2007; Constantinides and Ghosh, 2009).}
A concern with this approach is that the asset pricing data may be driven by other factors such as habits, rare disasters
and heterogeneous agents.\footnote{See Campbell and Cochrane (1999), Barro (2006) and Constantinides and Duffie (1996) for influential asset pricing
models based on these features.}

\footnote{See also Bloom et al., 2011, Fernandez-Villaverde et al., 2011, and Basu and Bundick (2011).}
is based on would, therefore, strengthen the case for this model.

We quantify the importance of growth-rate and uncertainty shocks using recently assembled data on aggregate consumption for a panel of 16 developed countries. We assume that certain features of consumption dynamics are common across countries. This allows us to estimate key parameters more accurately. An advantage of our approach is that our estimates are based purely on macroeconomic data. We therefore avoid the concern that our estimates of growth-rate and uncertainty shocks are engineered to fit the asset pricing data, as opposed to being a fundamental feature of the aggregate consumption data.

Our empirical model augments Bansal and Yaron’s model to allow for common variation in growth-rates and uncertainty across countries as well as country-specific shocks to growth rates and uncertainty. We identify a substantial common component to expected growth rates in our panel of developed countries. This common variation in growth rates is highly persistent. It captures the productivity speed-up and slow-down in the second half of the 20th century as well as several world recessions, such as those of 1979, 1990 and 2008. The country-specific growth-rate processes we identify are less persistent, but nevertheless yields movements in consumption that differ substantially from a random walk.

We also identify large and highly persistent common shocks to macroeconomic uncertainty. Our world uncertainty process captures the large but uneven rise and fall of volatility that occurred over the course of the 20th century. The “Great Moderation” identified by McConnell and Perez-Quiros (2000) is evident in our estimates. But we uncover several additional sharp swings in volatility, most recently a large increase associated with the “Great Recession.” We estimate substantial variation across countries in the timing and direction of uncertainty shocks. For example, uncertainty rose for several decades after World War II (WWII) in the U.K., while it fell in most countries over this period.

Another novel feature of our empirical model relative to earlier work is that we allow the growth-rate and uncertainty shocks to be correlated. We find that they are in fact substantially negatively correlated. In other words, negative shocks to growth rates tend to be associated with shocks that increase uncertainty. The 1960’s were both a period of high growth and low volatility, while in the 1970’s growth fell and uncertainty rose. More recently, during the recessions of 1990 and particularly 2008 growth fell and our estimates of uncertainty shot up.

Overall our empirical results based on macroeconomic data alone yield parameter values that are

---

6These findings line up well with those of Cogley (1990), who finds that long-run growth rates of output are more highly correlated across countries than one-year growth rates for nine of the countries we study.
quite consistent with calibrations of the long-run risks model designed to match key asset pricing moments (Bansal and Yaron, 2004; Bansal, Kiku, and Yaron, 2012). We analyze the asset pricing implications of our estimated model of consumption dynamics within the context of a representative agent endowment economy—following Lucas (1978) and Mehra and Prescott (1985)—and assume that agents have Epstein-Zin-Weil preferences (Epstein and Zin, 1989; Weil, 1990). Our model can match the observed equity premium and risk-free rate if agents have a coefficient of relative risk aversion (CRRA) of roughly 6.5 and an intertemporal elasticity of substitution (IES) of 1.5. For the same utility function parameters, the model without growth-rate and uncertainty shocks generates an equity premium that is more than an order of magnitude smaller. Bansal and Yaron (2004) match the equity premium with a CRRA of 10. On this metric, our estimates, thus, yield more long-run risk than their original calibration. Our model also does well when it comes to other key asset pricing moments such as the volatility of stock returns, the volatility of the risk-free rate, the Sharpe ratio for equity, the volatility and persistence of the price-dividend ratio on stocks and predictability of stock returns based on the price-dividend ratio on stocks.

Uncertainty shocks play an important role in generating movements in asset prices in our model. Shocks that raise expected future uncertainty lead stock prices to fall. And expected returns are predictably high following stock market declines provoked by such uncertainty shocks. Through this mechanism, our model is able to help explain the long-term predictability of stock returns (Campbell and Shiller, 1988; Fama and French, 1988; Hodrick, 1992; Cochrane, 2008; Binsbergen and Koijen, 2010). Our model also implies that price-dividend ratios should forecast volatility and consumption growth. We show that price-dividend ratios on stocks have substantial predictive power for future realized volatility of consumption growth in our sample of countries—extending earlier evidence by Bansal et al. (2005). We also extend related work by Lettau et al. (2004, 2008) that suggests that changes in macroeconomic volatility can explain a substantial fraction of low-frequency movements in price-dividend ratios on stocks. In the data, consumption growth is not forecastable by the price-dividend ratio (Beeler and Campbell, 2012). This suggests that investors may not have had full knowledge of the variation in growth prospects we estimate in real time (Croce, Lettau, and Ludvigson, 2010).

We analyze the quantitative implications of growth-rate and uncertainty shocks under the assumption that the CRRA is 6.5. This value is substantially lower than the standard parameterization in the long-run risks literature of CRRA = 10. However, this degree of risk aversion is high rela-

\footnote{However, Bansal, Kiku, and Yaron (2012) show that consumption growth is substantially forecastable in a VAR with the price-dividend ratio, the risk-free rate and consumption growth.}
tive to the values typically estimated in the microeconomics literature (Barsky et al., 1997; Chetty, 2006; Paravisini et al. 2010). Our findings, thus, leave ample “room” for additional factors, such as habit, heterogeneous agents, and rare disasters to play an important role in explaining the level and volatility of asset returns.

In addition to the work discussed above, our paper is related to several strands of work in macroeconomics and finance. A large body of work in macroeconomics has studied the long-run properties of output (Nelson and Plosser, 1982; Campbell and Mankiw, 1989; Cochrane, 1988; Cogley, 1990) and variation in the volatility of output growth (McConnell and Perez-Quiros, 2000; Blanchard and Simon, 2001; Stock and Watson, 2002; Ursua, 2010). Our paper builds heavily on the large and growing literature on long-run risks as a framework for asset pricing pioneered by Kandel and Stambaugh (1990). We consider a simple representative agent asset pricing framework with known parameter values, taking the consumption process as given. Several theoretical papers extend on this framework, studying the production-based microfoundations for long run risks (e.g., Kaltenbrunner and Lochstoer, 2010; Kung and Schmid, 2011), the asset pricing implications of parameter learning (e.g., Collin-Dufresne, Johannes, and Lochstoer, 2012), deviations from the representative agent framework (e.g., Garleanu and Panageas, 2010), and frameworks where utility depends on more than just consumption (e.g., Uhlig, 2007).

The paper proceeds as follows. Section 2 discusses the data we use. Section 3 presents the empirical model. Section 4 discusses our estimation strategy. Section 5 presents our empirical estimates. Section 6 studies the asset-pricing implications of our model. Section 7 concludes.

2 Data

We estimate our model using a dataset on long-term consumer expenditures recently constructed by Robert Barro and Jose Ursua, and described in detail in Barro and Ursua (2008). Our sample includes 16 countries: Australia, Belgium, Canada, Denmark, Finland, France, Germany, Italy, [Note: The text continues with more detailed information about the data and the limitations of the dataset.]
Our consumption data is an unbalanced panel with data for each country starting between 1890 and 1914. Our sample period ends in 2009. Figure 1 plots our data series for France. In analyzing the asset pricing implications of our model, we also make use of total returns data on stocks and bills as well as dividend yields on stocks from Global Financial Data (GFD) and data on inflation from Barro and Ursua (2008).

3 An Empirical Model of Growth-Rate and Uncertainty Shocks

Building on the work of Bansal and Yaron (2004), we model the logarithm of the permanent component of per capita consumption in country $i$ at time $t+1$—denoted $\tilde{c}_{i,t+1}$—as evolving in the following way:

$$
\Delta \tilde{c}_{i,t+1} = \mu_i + x_{i,t} + \xi_i x_W,t + \eta_{i,t+1},
$$

$$
x_{i,t+1} = \rho x_{i,t} + \epsilon_{i,t+1},
$$

$$
x_{W,t+1} = \rho_W x_{W,t} + \epsilon_{W,t+1}.
$$

Permanent consumption growth is governed by three shocks: a random-walk shock ($\eta_{i,t+1}$), and two shocks that have persistent effects on the growth rate of consumption—one of which is country specific ($\epsilon_{i,t+1}$) and one of which is common across all countries ($\epsilon_{W,t+1}$). The persistence of the effects of the last two of these shocks to consumption growth is governed by AR(1) processes $x_{i,t+1}$ and $x_{W,t+1}$, respectively. We allow the different countries in our sample to differ in their sensitivity to the world growth rate process. This differing sensitivity is governed by the parameter $\xi_i$.

The volatility of the three shocks affecting permanent consumption growth is time varying and governed by two AR(1) stochastic volatility processes:

$$
\sigma^2_{i,t+1} = \gamma (\sigma^2_{i,t} - \sigma^2_i) + \omega_{i,t+1},
$$

$$
\sigma^2_{W,t+1} = \gamma (\sigma^2_{W,t} - \sigma^2_W) + \omega_{W,t+1},
$$

where $\sigma^2_{i,t+1}$ is a country-specific component of stochastic volatility and $\sigma^2_{W,t+1}$ is a common component of stochastic volatility. We refer to the innovations to these stochastic volatility processes—$\omega_{i,t+1}$ and $\omega_{W,t+1}$—as uncertainty shocks.

The common component of stochastic volatility $\sigma^2_{W,t+1}$ affects the volatility of all three of the shocks to permanent consumption. The idea here is that when world uncertainty rises this affects...
the volatility of all shocks to permanent consumption. The country specific component of stochastic volatility \( \sigma^2_{i,t+1} \), however, only affects the country specific shocks. Variation in this component, therefore, represents deviations in the uncertainty faced by a particular country from that faced by countries on average. More specifically, we assume that \( \text{var}_t(\epsilon_{W,t+1}) = \sigma^2_{W,t} \), \( \text{var}_t(\epsilon_{i,t+1}) = \sigma^2_{i,t} + \sigma^2_{W,t} \), and \( \text{var}_t(\eta_{i,t+1}) = \chi^2_i \cdot (\sigma^2_{i,t} + \sigma^2_{W,t}) \), where \( \chi_i \) governs the relative volatility of the two country specific shocks, \( \epsilon_{i,t+1} \) and \( \eta_{i,t+1} \).

We allow for correlation between the growth-rate shocks and the uncertainty shocks. This is meant to capture the possibility that times of high uncertainty may also tend to be times of low growth. Specifically, we allow the country-specific growth-rate shock \( \epsilon_{i,t+1} \) and the shock to the country specific stochastic volatility process \( \omega_{i,t+1} \) to be correlated with a correlation coefficient of \( \lambda \). We also allow the world growth-rate shock \( \epsilon_{W,t+1} \) and the world uncertainty shocks \( \omega_{W,t+1} \) to be correlated with a correlation coefficient of \( \lambda_W \).

To summarize, we assume the following distributions for the random-walk, growth-rate and uncertainty shocks:

\[
\eta_{i,t+1} \sim N(0, \chi^2_i \cdot (\sigma^2_{i,t} + \sigma^2_{W,t})),
\]

\[
\begin{bmatrix}
\epsilon_{i,t+1} \\
\omega_{i,t+1}
\end{bmatrix} \sim N \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma^2_{i,t} + \sigma^2_{W,t} & \lambda \sigma \sigma_{\omega,W} \\
\lambda \sigma_{\omega} \sigma_{\omega_W} & \sigma^2_{\omega,W} \end{bmatrix} \right),
\]

\[
\begin{bmatrix}
\epsilon_{W,t+1} \\
\omega_{W,t+1}
\end{bmatrix} \sim N \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma^2_{W,t} & \lambda W \sigma_{W,t} \sigma_{\omega,W} \\
\lambda W \sigma_{W,t} \sigma_{\omega,W} & \sigma^2_{\omega,W} \end{bmatrix} \right).
\]

To avoid negative variances, we truncate the process for \( \sigma^2_{W,t+1} \) at a small positive value \( \zeta \) and we truncate the process for \( \sigma^2_{i,t+1} \) such that \( \sigma^2_{i,t+1} > \zeta - \sigma^2_{W,t} \).

We allow parameters to vary across countries whenever our dataset contains enough information to make this feasible. For example, we allow \( \sigma^2_{i} \) to differ across countries. This allows some countries to have permanently higher or lower volatility of macroeconomic shocks than others. However, as Bansal and Yaron (2004) emphasize, some of the key parameters of the long-run risks model are difficult to estimate precisely using data from a single country, even with over 100 years of data. For these parameters, we rely on the panel structure of the data set and assume that they are equal for all countries in our data set. The parameters we make this pooling assumption for are: the persistence of the growth-rate components \( \rho \) and \( \rho_W \), the persistence of the stochastic volatility processes \( \gamma \),

\[^{11}\text{For world stochastic volatility, this means that when an } \omega_{W,t+1} \text{ is drawn that would yield a value of } \sigma^2_{W,t+1} < \zeta, \text{ we set } \sigma^2_{W,t+1} = \zeta. \text{ This implies that the innovations to the } \sigma^2_{W,t+1} \text{ have a positive mean when } \sigma^2_{W,t+1} \text{ is close to } \zeta. \text{ For the estimated values of the parameters of our model (baseline estimation), } \sigma^2_{W,t+1} = \zeta \text{ about 9.2% of the time.}\]
the volatility of the uncertainty shocks $\sigma^2_\omega$ and $\sigma^2_{W,\omega}$, the average volatility of the world stochastic volatility process $\sigma^2_W$, and the correlations between the growth-rate and uncertainty shocks $\lambda$ and $\lambda_W$.\(^{12}\)

We allow measured consumption—denoted $c_{i,t}$—to differ from permanent consumption $\tilde{c}_{i,t}$ because of two transitory shocks:

$$c_{i,t+1} = \tilde{c}_{i,t+1} + \nu_{i,t+1} + I_{i,t+1}^d \psi_{i,t+1}^d. \quad (8)$$

The first of these shocks $\nu_{i,t+1}$ is mainly meant to capture measurement error. We assume that this shock is distributed $N(0, \sigma^2_{i,t,\nu})$, where the volatility of this shock is allowed to differ before and after 1945. By incorporating this break in the volatility of $\nu_{i,t+1}$ we can capture potential changes in national accounts measurement around this time (Romer, 1986; Balke and Gordon, 1989). This is empirically important since it avoids the possibility that our estimates of the high persistence of macroeconomic uncertainty arise spuriously from these changes in measurement procedures.

The second shock $I_{i,t+1}^d \psi_{i,t+1}^d$ captures disasters. We do not estimate the timing of disasters in this paper. Instead, the dummy variable $I_{i,t}^d$ is set equal to one in periods identified as disaster periods by Nakamura et al. (2010) and during a two year recovery period after each such episode and zero otherwise.\(^{13}\) The disaster shock $\psi_{i,t}^d$ is distributed $N(\mu_d, 1)$. We fix the variance of $\psi_{i,t}^d$ at 1 (a large value), to ensure that this shock “soaks up” all transitory variation in consumption during the disaster periods. Were we to exclude the disaster shock, we would estimate substantially higher volatilities of the stochastic volatility processes $\sigma^2_{i,t+1}$ and $\sigma^2_{W,t+1}$.

4 Estimation

The model presented in section 3 contains a large number of unobserved state variables, since it decomposes consumption into several unobserved components. We estimate the model using Bayesian MCMC methods.\(^{14}\) To carry out our Bayesian estimation we need to specify a set of priors

\(^{12}\)Notice also, that we assume that the same parameter ($\gamma$) governs the persistence of both the common and country-specific components of stochastic volatility. We do this because there is insufficient information in our dataset to estimate a separate parameter for the persistence of world volatility.

\(^{13}\)Nakamura et al. (2010)’s results indicate that there is unusually high growth after disasters—i.e., recoveries—but that this unusually high growth dies out rapidly—it has a half-life of 1 year. By allowing for a two year recovery period after disasters, we allow the disaster shocks in our model to capture the bulk of the unusually high growth after disasters and avoid having this growth variation inflate our estimates of long-run risks.

\(^{14}\)Our algorithm samples from the posterior distributions of the parameters and unobserved states using a Gibbs sampler augmented with Metropolis steps when needed. This algorithm is described in greater detail in appendix A. The estimates discussed in section 5 for the three versions of the model, are based on four independent Markov chains each with 5 million draws or more with the first 450,000 draws from each chain dropped as “burn-in”. To assess
on the parameters of the model. We choose highly dispersed priors for all the main parameters of the model to minimize their effect on our inference. The full set of priors we use is:

\[
\begin{align*}
\rho & \sim U(0.005, 0.995), & \rho_W & \sim U(0.005, 0.995), \\
\gamma & \sim U(0.005, 0.98), & \sigma^2_W & \sim U(10^{-8}, 10^{-2}), \\
\sigma^2_\omega & \sim U(10^{-10}, 10^{-6}), & \sigma^2_{W,\omega} & \sim U(10^{-10}, 10^{-6}), \\
\lambda & \sim U(-0.995, 0.995), & \lambda_W & \sim U(-0.995, 0.995), \\
\xi & \sim U(10^{-4}, 10), & \chi^2 & \sim U(10^{-4}, 25), \\
\sigma^2_\nu & \sim U(10^{-8}, 10^{-2}), & \sigma^2_{\nu,i} & \sim U(10^{-8}, 10^{-2}), \\
\mu_i & \sim N(0.015, 1), & \mu_d & \sim N(0, 1),
\end{align*}
\]

except that we normalize \( \xi_{US} = 1 \) to identify the scale of the world stochastic volatility process.

We assume that the initial values of \( x_{i,t}, x_{W,t}, \sigma_{i,t} \), and \( \sigma_{W,t} \) are drawn from their unconditional distributions. We assume that the initial value of \( \tilde{c}_{it} \) for each country is drawn from a highly dispersed normal distribution centered on the initial observation for \( c_{i,t} \). It can be shown that the model is formally identified except for a few special cases in which multiple shocks have zero variance.

## 5 Empirical Results

Our baseline empirical results are for the full model described in section 3 for the full sample period 1890-2009. We also report results for a simplified version of the model in which we shut down the world growth-rate and volatility components as well as the correlation between the country-specific growth-rate and volatility shocks. We refer to this latter model as the “simple model.” Tables 1-3 present parameter estimates for these three cases. For each parameter, we present the prior and posterior mean and standard deviation. We refer to the posterior mean of each parameter as our point estimate for that parameter.

We estimate a highly persistent world growth-rate process in our baseline model. The autoregressive coefficient for the world growth-rate component is estimated to be \( \rho = 0.83 \), implying a half-life of 3.8 years. The country specific growth-rate process is estimated to be less persist in our model. The autoregressive coefficient for the country-specific growth-rate component is estimated to be \( \rho = 0.56 \), implying a half-life of 1.2 years. Table 2 compares these estimates to the calibration of the persistence of the growth-rate component in Bansal and Yaron (2004) and Bansal et al. (2012). The persistence of our world growth-rate component is estimated to be substantially larger than the
persistence of the growth-rate component in these papers. In the simple model, the persistence of the (country-specific) growth-rate component is estimated to be $\rho = 0.68$, which implies a half-life of 1.8 years. This illustrates that allowing for a world growth-rate component is important in capturing the low-frequency variation in growth in our dataset.

Figure 2 plots the impulse response of consumption to our estimated growth-rate processes as well as to the random-walk shock. The figure shows clearly how different the effects of the growth-rate shocks are from those of the random-walk shock. After a country-specific growth-rate shock, consumption continues to grow for several periods and eventually rises by more than two times the initial size of the shock with the bulk of the growth occurring in the first 5 years. After a world growth-rate shock, continuing growth in subsequent periods leads the eventual impact of the shock on consumption to be six times its initial impact with roughly a third of that growth occurring more than 5 years after the shock.

Figure 3 presents our estimate of the world growth-rate process. The most striking feature of this process is its high values in the 1950’s, 60’s and early 70’s. This captures the persistently high growth seen in many countries in our sample in the 3rd quarter of the 20th century. The world growth-rate process also captures several major recessions such as the 1979 recession following the spike in oil prices that accompanied the Iranian Revolution, the recession of 1990 following, among other events, the unification of Germany and the accompanying tightening of German monetary policy, and the 2008 recession following the sharp fall in house prices in several countries, associated collapse of major financial institutions and turmoil in financial markets.

We estimate uncertainty shocks to be far more persistent than the growth-rate shocks. Tables 1 reports that our estimate of the autoregressive coefficient for the uncertainty processes in the baseline estimation is $\gamma = 0.970$. This implies that uncertainty shocks in the baseline case have a half-life of 22.8 years (Table 2). This estimate lies between the 4.4 year calibration of Bansal and Yaron (2004) and the 57.7 year calibration of Bansal et al. (2012). Uncertainty shocks are also estimated to be highly persistent in the simple model and in the post-WWII sample. For these cases, we estimate half-lives of 13.5 years and 18.2 years, respectively.

Figure 4 presents our estimates of the evolution of the world stochastic volatility process ($\sigma_{W,t}$). In studying this figure, it is important to keep in mind that our model attributes much of the volatility in the first half of our sample to disasters and measurement error. We estimate that world

\footnote{It is intriguing that this growth spurt so closely followed World War II. It is tempting to infer that this high growth is due to post-war reconstruction. However, for most countries, the vast majority of the unusually high growth during this period occurred in years when consumption (and output) had surpassed its pre-WWII trend-adjusted level.}
volatility was high in the early post-WWII period and has been on an uneven downward trend since then. World volatility fell a great deal in the 1960’s, but was high again in the 1970’s and early 1980’s. It fell sharply in the mid-to-late 1980’s but was relatively high in the early 1990’s — likely due to the ERM crisis in Europe. From 1995 to 2007 the world experienced a long period of relative tranquility with volatility falling sharply towards the end of this period to record lows. At the end of our sample period, world volatility rose sharply once again.

Comparing Figures 3 and 4, it is evident that the world growth-rate process and the world stochastic volatility process are negatively correlated. Our model allows explicitly for a correlation between shocks to these processes ($\lambda_W$). Table 1 reports that our estimate of this correlation is -0.25. We also estimate a common correlation between the country-specific growth-rate processes and country-specific volatility processes in our data and find this correlation to also be -0.40. Our estimates, thus, strongly suggest that periods of high volatility are also periods of low growth.

Despite the large common variation in volatility displayed in Figure 4, we estimate a substantial amount of heterogeneity in the evolution of volatility across countries. Figure 5 presents our estimates of the evolution of the volatility process for the U.S., the U.K. and Canada ($\sigma_{i,t}^2 + \sigma_W^2 t^{1/2}$ in our notation). For the United States our results reflect the “long and large” decline in macroeconomic volatility documented by Blanchard and Simon (2001) and well as the rather abrupt decline in volatility in the mid-1980’s documented by McConnell and Perez-Quiros (2000) and Stock and Watson (2002). The experience of the U.K. is quite different. Volatility in the U.K. was lower in the early part of the 20th century (excluding disasters), but then rose substantially over the first three decades after WWII. Volatility in the U.K. began falling much later than in the U.S. and has remained elevated relative to volatility in the U.S. ever since 1960. In contrast, volatility in Canada fell much more abruptly in the 1950’s and early 1960’s than volatility in the U.S. and was substantially below U.S. volatility in the 1960’s, 1970’s and early 80’s at which point U.S. volatility converged down to similarly low levels.

One feature of our results that differs markedly from the calibrations of the long-run risks model used in Bansal and Yaron (2004) and Bansal et al. (2012) is that the growth-rate shocks we estimate are substantially more volatile. Recall that the parameter $\chi_i$ governs the relative volatility of the random-walk shock ($\eta_{i,t}$) and the growth-rate shock ($\epsilon_{i,t}$). Results for this parameter as well as other country specific parameters are reported in Table 3. For the median country, we estimate $\chi_i$ to be 0.81, while we estimate a value of 1.16 for the United States.\textsuperscript{16} Our estimates thus imply that

\textsuperscript{16}Estimates for all 16 countries for our baseline case are presented in the appendix (Table A.1).
the growth-rate shocks and the random-walk shocks are roughly equally volatile. Bansal and Yaron (2004) and Bansal et al. (2012) calibrate the growth-rate shock to be only about 5% as volatile as the random-walk shock.

We allow countries to differ in their sensitivity to the world growth-rate process. The parameter $\xi_i$ governs this sensitivity. We fix $\xi_{US} = 1$, implying that for other countries this parameter can be interpreted as their sensitivity to world shocks relative to the sensitivity of the U.S. to these shocks. For the median country, our estimate of $\xi_i = 1.51$. In particular, many continental European countries have values of $\xi_i$ that are substantially larger than one (see Table A.1). This heterogeneity in sensitivity to the world-growth rate shock is one source of heterogeneity in risk-premia across countries in our asset-pricing calculations in section 6. We estimate a substantial decline in the volatility of transitory shocks $\sigma_{\nu,i}$ after 1945 in most countries. This change likely reflects in part changes in national accounts measurement, as we discuss in section 3.17

One potential concern with our results is that they might be influenced our treatment of disasters in the early part of our sample. Another potential concern is the quality of the data for the period before World War II may be lower than for the more recent period. To address these concerns, we estimate our model on data starting in 1950. Tables 1 and 3 report our parameter estimates for this case. It yields results that are very similar to our baseline estimation along most dimensions. The main deviation is that in this case we estimate a smaller and less volatile world stochastic volatility process and larger values of the sensitivity to the world growth-rate shock for most countries. However, the posterior standard deviation of several key parameters increases substantially—in particular, the standard deviation of the sensitivity to the world growth-rate—reflecting the much smaller sample. For the median country, the degree to which consumption growth is driven by the world growth-rate shock rises since the increase in the sensitivity to the world growth-rate shock is larger than the decrease in the volatility of the world growth-rate shocks.

5.1 Evaluating Model’s Fit to Reduced Form Statistics

To assess the fit of our model, we consider reduced from statistics on the persistence and cross-country correlation of consumption growth and the volatility of consumption growth. Table 4 present estimates of autocorrelations, cross-country correlations and variance ratios in the data and variance ratios in the data and variance ratios in the data and variance ratios in the data

17Ursua (2010) argues—based on methods developed by Romer (1986)—that this change also reflects changes in macroeconomic fundamentals. Since transitory shocks turn out to be relatively unimportant for asset pricing, the choice of whether to treat this change as a consequence of measurement or fundamental shocks plays a small role in our asset pricing analysis.
in the model. Both for the data and the model, we exclude disasters.\footnote{For the data, we do this by subtracting from the data the effect of disasters estimated from our model. This yields series for consumption that smoothly “interpolate” through disasters.}

Consider first the autocorrelation of consumption growth. In the data and the model for the median country these are positive but relatively small. In all cases, the autocorrelation in the data is well within the 90\% probability interval from the model. For the U.S., the estimated autocorrelations in the data oscillate around zero.\footnote{Estimated on the post-WWII sample, the autocorrelations for the U.S. oscillate less and are slightly negative at horizons longer than one year.} Again, the model implies autocorrelations that line up well with the data. Despite assigning an important role to long-run risks, our estimated model does not yield excessive short term autocorrelation in the growth rate of consumption because the model also features transitory shocks to the level of consumption, which generate offsetting negative correlation in short term growth rates.

The cross-country correlation of consumption growth for the median country is estimated to be substantial and to grow with the horizon. The median one-year cross-country correlation is 0.23, while it is 0.44 at the five year horizon and 0.56 at the ten year horizon. The model is able to capture both the magnitude and the increasing pattern of this cross-country correlation through the world growth-rate process. The correlation of the U.S. with other countries in our sample is somewhat smaller than for the median country both in the data and in the model.

Table 4 also reports estimates of variance ratios for consumption growth and the volatility of consumption growth at the 15 year horizon for the median country and for the United States. Variance ratios above one indicate reduced form evidence for positive autocorrelation of consumption growth and volatility. The definition and intuition for these statistics is discussed in more detail in appendix B. In the data, the variance ratio for consumption growth for the median country is 1.69, substantially above one. The average across country is even higher at 2.28. For the U.S. it is somewhat smaller but still above one.\footnote{We have also calculated these variance ratios including disasters and they are lower. Excluding disasters raises the variance ratio of consumption growth because disasters are typically followed by significant recoveries (Kilian and Ohanian, 2002; Nakamura et al., 2010). Ursua (2010) presents a related analysis. Rather than filtering the data the way we do, he excludes “outlier” growth observations. This simpler procedure also yields substantially larger variance ratios than raw consumption growth in his broader sample.} These high variance ratios provide reduced form evidence for positive autocorrelation of growth rates. Our model captures this well. For the median country, the model generates a 15-year variance ratio of 2.69. The variance ratio of realized volatility is substantially larger than one both in the median country and in the United States. Again, our model is able to capture this feature of the data well.
6 Asset Pricing

We analyze the asset pricing implications of the model of aggregate consumption described in section 3 within the context of a representative consumer endowment economy with Epstein-Zin-Weil preferences (Epstein and Zin, 1989; Weil, 1990). For this preference specification, Epstein and Zin (1989) show that the return on an arbitrary cash flow is given by the solution to the following equation:

\[ E_t \left[ \beta^\theta \left( \frac{C_{i,t+1}}{C_{i,t}} \right)^{(-\theta/\psi)} R_{c,t+1}^{-(1-\theta)} R_{t,t+1} \right] = 1, \tag{9} \]

where \( R_{i,t+1} \) denotes the gross return on an arbitrary asset in country \( i \) from period \( t \) to period \( t + 1 \), \( R_{c,t+1} \) denotes the gross return on the agent’s wealth, which in our model equals the endowment stream. The parameter \( \beta \) represents the subjective discount factor of the representative consumer. The parameter \( \theta = \frac{1-\gamma}{1-\psi} \), where \( \gamma \) is the coefficient of relative risk aversion (CRRA) and \( \psi \) is the intertemporal elasticity of substitution (IES), which governs the agent’s desire to smooth consumption over time.

We begin by calculating asset prices for two assets: a risk-free one-period bond and a risky asset we will use to represent equity. The risk-free one-period bond has a certain pay-off of one unit of consumption in the next period. We follow Bansal, Kiku, and Yaron (2012) in modeling equity as having a levered exposure to the stochastic component of permanent consumption. Specifically, the growth rate of dividends for our equity claim is

\[ \Delta d_{t+1} = \mu + \phi(x_{i,t} + \xi_i W_{t} + \eta_{i,t}), \tag{10} \]

where \( \phi \) is the leverage ratio on expected consumption growth (Abel, 1999). We base our analysis on the posterior mean estimates for the baseline case from section 5. We therefore abstract from learning, doubt and fragile beliefs (Timmermann, 1993; Pastor and Veronesi, 2009; Hansen, 2007; Hansen and Sargent, 2010). These issues are potentially important in our context, given the difficulty of estimating long-run risks, both for the econometrician, and the economic agent (see, e.g., Croce et al., 2010).

The asset-pricing implications of our model with Epstein-Zin-Weil (EZW) preferences cannot be derived analytically. We solve for asset prices in our model using standard grid-based numerical methods of the type used, e.g., by Campbell and Cochrane (1999) and Wachter (2005).

\[ \text{We solve the integral in equation (9) on a grid. Specifically, we start by solving for the price-dividend ratio for a consumption claim. In this case we can rewrite equation (9) as } \]

\[ PDR_{t+1}^C = E_t[\Delta C_{t+1}]. \]

\[ \text{where } PDR_{t+1}^C \text{ denotes the price dividend ratio of the consumption claim. We specify a grid for } PDR_{t+1}^C \text{ over the state space. We} \]
We choose a subjective discount factor of \( \beta = 0.990 \) to fit the observed average risk-free rate in our baseline specification. We choose a CRRA of \( \gamma = 6.5 \) to match the U.S. equity premium in our baseline specification. We follow the long-run risks literature in choosing an IES of \( \psi = 1.5 \) (Bansal and Yaron, 2004; Bansal et al., 2012).\(^{22}\) We follow Bansal and Yaron (2004) in setting leverage of \( \phi = 3 \). We calculate asset prices for the non-disaster component of consumption. We do this to focus attention on the asset-pricing implications of long-run risks. We present asset pricing results for the post-WWII estimation of our model—a sample without major disasters in our sample of countries—in an appendix (Table A.2).\(^{23}\)

6.1 The Effects of Long-Run Risks on Asset Prices

Figure 6 presents impulse responses for the return on equity and the risk-free rate to a world growth-rate shock. A positive world growth-rate shock yields a large positive return on equity on impact. This positive return reflects the balance of two opposing forces. On the one hand, the shock raises expected future dividends on equity, which pushes up stock prices. On the other hand, since consumption growth is expected to be high for some time, agents’ desire to save falls, which pushes down all asset prices. If agents are sufficiently willing to substitute consumption over time (IES > 1), as we assume, the first of these effects is stronger than the second for equity and the price of equity rises on impact. In the periods after the shock, returns on equity and the risk-free rate are higher than average because of agents’ reduced desire to save.

Figure 7 presents impulse responses for the return on equity and the risk-free rate to an uncertainty shock. A shock that increases economic uncertainty yields a large negative return on equity on impact. As with the growth-rate shock, there are two opposing forces that together determine the response of stock prices. The increase in economic uncertainty makes stocks riskier — raises the equity premium. This tends to depress their value. However, the increase in uncertainty also increases the desire of agents to save. This tends to raise the price of all assets. With CRRA > 1 and IES > 1, the first force is stronger than the second and the price of stocks falls on impact (Campbell, then solve numerically for a fixed point for \( PDR_{C} \) as a function of the state of the economy on the grid. We can then rewrite equation (9) for other assets as \( PDR_{t} = E_{t}[f(\Delta C_{t+1}, \Delta D_{t+1}, PDR^{C}_{t+1}, PDR_{t+1})] \), where \( PDR_{t} \) denotes the price dividend ratio of the asset in question and \( \Delta D_{t+1} \) denotes the growth rate of its dividend. Given that we have already solved for \( PDR^{C}_{t} \), we can solve numerically for a fixed point for \( PDR_{t} \) for any other asset as a function of the state of the economy on the grid.

\(^{22}\)There is little agreement in the macroeconomics and finance literatures on the appropriate value for the IES. Hall (1988) and Campbell (1999) estimate the IES to be close to zero. However, Hansen and Singleton (1982), Bansal and Yaron (2004), Gruber (2006), Hansen et al. (2007) and Nakamura et al. (2010) argue for values of the IES above one.

\(^{23}\)The asset pricing implications of disaster risk has been the focus of a large recent literature (see, e.g., Barro, 2006, and Nakamura, et al., 2010).
In the periods after the shock, the equity premium remains elevated because uncertainty has risen. A one standard deviation shock to $\omega_{W,t}$ raises the equity premium by roughly 0.6% in the period after the shock.

Notice that in our model neither the growth-rate shock nor the uncertainty shock affect consumption growth on impact. For an agent with power utility, these shock would therefore not affect marginal utility on impact. This implies that agents with power utility would not demand a risk premium on stocks as compensation for exposure to these shocks. With EZW utility, however, marginal utility depends not only on current consumption but also on news about future consumption. In equation (9), this is captured by the presence of the return on wealth—$R_{c,t+1}$. Since negative growth-rate shocks and shocks that increase uncertainty imply negative returns on wealth on impact, they increase marginal utility. Households are, thus, willing to pay a premium for assets that provide insurance against growth-rate and uncertainty shocks. Conversely, they demand a risk premium for holding assets that expose them to these shocks.

6.2 Risk-Premia and Return Volatility

Table 5 presents key asset pricing statistics in the data and for our baseline specification of the model. The table presents results for the U.S. and for the median country in our sample. With a CRRA equal to 6.5, our model can match the observed equity premium for the United State. This contrasts sharply the results of Mehra and Prescott (1985). They show that a model without long-run risks and with power utility generates equity premia that are more than 10 times too small for values of the CRRA below 10. Our result furthermore contrasts the results of Bansal and Yaron (2004) and Bansal et al. (2012), who match the equity premium for a CRRA of 10. On this metric, the amount of long-run risks we estimate is, thus, larger than that implied by the original calibrations of the long-run risks model. The estimated model also does well along a number of other key dimensions. It generates highly volatile returns on equity. The standard deviation of equity returns for the U.S. is 18% in the model versus 17% in the data. The model also matches the low level of the risk-free rate seen in that data and it generates a very stable return on the risk-free asset. The standard deviation of the risk-free rate in the model is 1.6% for the U.S. The standard deviation of ex post real returns on U.S. T-bills (our empirical measure of the risk-free rate) is 3.3%. Since the model does not incorporate inflation risk, it is appropriate that the model yields a lower number than the

---

24 This implication of EZW preferences is illustrated elegantly by the decomposition developed by Borovicka et al. (2011).
data along this dimension. The model can also generate large and very persistent movements in the
price-dividend ratio on stocks. For the U.S., the standard deviation of the price-dividend ratio in
the model is 0.3 and its first-order autocorrelation is 0.85, while these statistics are 0.4 and 0.9 in
the data, respectively.\textsuperscript{25}

Table 6 presents results on the equity premium and the risk free rate for all 16 countries in our
sample. For the equity premium, we report results for several “counter-factual” parameterizations.
This sheds light on the relative importance of the different features we introduce in our model. The
first set of results are for the full model (baseline case). It generates equity premia ranging from
8-23% with an average equity premium of 13.7%. The second case preserves the baseline parameter
values of the full model except that it eliminates the uncertainty shocks. This “constant volatility”
model yields equity premia that are roughly half as large as the full model. This illustrates the
important role uncertainty shocks play for asset prices in our model. In the the third case eliminates
all long-run risks and re-calibrate the volatility of the random-walk shocks to match the volatility of
$\Delta \tilde{c}_{t}$. This case corresponds closely to the model considered by Mehra and Prescott (1985), and we
refer to this as the Mehra-Prescott model. It generates equity premia that are more than an order
of magnitude smaller than those generated by the full model. Clearly, growth-rate and uncertainty
shocks of the persistence and magnitude we estimate in the data have a first order effect on the
equity premium.

We estimate a negative correlation between growth-rate and uncertainty shocks—i.e., negative
growth-rate shocks tend to be associated with shocks that raise economic uncertainty. Since negative
growth-rate shocks and shocks that increase uncertainty both raise marginal utility, being hit by
both at the same time is particularly painful for the representative agent. This implies that the
negative correlation between these two shocks contributes positively to the equity premium in our
model. We have calculated asset prices for a case with $\lambda = \lambda_W = 0$ but keeping other parameters
unchanged. This yields an equity premium that is 0.8 percentage points smaller for the U.S. than
our baseline case.

Finally, we analyze the term structure implications of our model. We approximate long-term
bonds by a perpetuity with coupon payments that decline over time by 10% per year. This yields

\textsuperscript{25}Table A.2 presents analogous results to Table 5 for our two alternative specifications. The simple model generates
a slightly smaller equity premium than the baseline case—roughly 4%. This is due to the fact that the simple
model doesn’t capture the persistent component of consumption growth that the baseline case captures with the world
component. The simple model matches the equity premium for a CRRA of roughly 10. The post-WWII case generates
very similar results for the U.S. but a larger equity premium for the median country. This is due to the very high
value of the sensitivity to the world growth-rate shock that is estimated for the median country.
a bond with a duration similar to that of 10-year coupon bonds. In our model, the term-premium for this real long-term bond is -2.0%. Piazzesi and Schneider (2006) document that the real yield curve in the United Kingdom has been downward sloping, while it has been mostly upward sloping in the United States. They caution, however, that this evidence is hard to assess because of the short sample and poor liquidity in the U.S. TIPS market.\footnote{Building on Alvarez and Jermann’s (2005) analysis of the implication of the term structure for the properties of the stochastic discount factor, Koijen et al. (2010) emphasize that the positive autocorrelation of growth rates in the long-run risk model implies that the model has a downward sloping term structure of real bond yields. Binsbergen et al. (2010a,b) show that short term dividend strips on the aggregate stock market have substantially higher expected returns than the stock market as a whole. (The price of a k-year dividend strip is the present value of the dividend paid in k years.) They point out that this fact is difficult to match using the original calibration of the long-run risk model proposed by Bansal and Yaron (2004). Croce, Lettau, and Ludvigson (2010) show that a model with long-run risk shocks that agents do not observe directly but must instead learn about over time can generate high excess returns on short-term assets relative to long-term assets.}

### 6.3 Predictability of Returns, Consumption and Volatility

A large literature in finance has argued that a high price-dividend ratio predicts low stock returns (Campbell and Shiller, 1988; Fama and French, 1988; Hodrick, 1992; Cochrane, 2008; Binsbergen and Koijen, 2010).\footnote{The statistical significance of return predictability has been hotly debated (see, e.g., Stambaugh, 1999; Ang and Bekaert, 2007). Recent work by Lewellen (2004) and Cochrane (2008) has exploited the stationarity of price-dividend ratios and the lack of predictability of dividend growth to develop more powerful tests of return predictability. These tests reject the null of no predictability of returns at the 1-2% level.} Leading asset pricing models differ in their implications about return predictability. In the long-run risks model, uncertainty shocks cause variation in the price-dividend ratio on stocks that forecasts stock returns. More generally, variation in the price-dividend ratio on stocks comes from two sources in the long-run risks model: growth-rate shocks and uncertainty shocks. This implies that the price-dividend ratio on stocks should forecast not only future returns on stocks but also future volatility and future consumption growth.

Table 7 presents results on the predictability of five-year excess returns on equity, realized volatility and consumption growth in our estimated models. We estimate equations of the following form

$$y_{i,t+5} = \alpha_i + \beta_i pd_{i,t} + \epsilon_{i,t+5},$$

where $pd_{i,t}$ denotes the logarithm of the price-dividend ratio on equity and $y_{i,t+5}$ is one of three things: the five-year excess return on stocks, five-year realized volatility or five-year consumption growth.\footnote{We follow Bansal et al. (2005) in using the absolute value of the residual from an AR(1) regression for consumption growth as our measure of realized volatility and summing this over five years.} We estimate these regressions in the data for the countries in our sample, and we run the same regressions on simulated datasets of the same length (120 years) from our baseline estimation.
and our simple model. We report the median from 1000 such simulations, as well as the 5% and 95% quantiles. For comparison, Table 7 also presents the degree of predictability of these variables in the models of Bansal and Yaron (2004) and Bansal et al. (2012).

The first panel of Table 7 presents results on the predictability of excess returns. Our point estimates imply a large degree of predictability of returns in the U.S. data. The regression coefficient on the price-dividend ratio is -0.41 and the R-squared of the regression is 0.24. We estimate less predictability of returns for the median country in our sample—regression coefficient of -0.30 and R-squared of 0.11. Our baseline case generates a median regression coefficient of -0.40 and a median R-squared of 0.10. The simple model yields similar results. Our model can thus account for a large fraction of the predictability of excess 5-year stock returns seen in the data. Our estimated model generates more predictability of excess stock returns that do the calibrations of the long-run risks model in Bansal and Yaron (2004) and Bansal et al. (2012).

The second panel of Table 7 presents results on the predictability of volatility. We find that the price-dividend ratio on stocks has substantial predictive power for realized volatility of consumption growth. For the U.S., the regression coefficient is -0.81 and the R-squared 0.32. For the median country in our sample, predictability of volatility is smaller, but nevertheless substantial—regression coefficient of -0.38 and an R-squared of 0.19. These results are in line with earlier results by Bansal et al. (2005). Our model generates predictability of volatility that lines up well with the data. The regression coefficients for our baseline case is -0.37 and the R-squared is 0.07, while for the simple model we get a regression coefficient of -0.91 and an R-squared of 0.12. The values for the U.S. and for the median country are well within the 90% confidence interval we construct.

Our model also implies a low frequency link between stock prices and macroeconomic uncertainty. Figure 8 plots our estimate of the evolution of economic uncertainty in the U.S. along with the dividend-price ratio on stocks. The figure illustrates the comovement between economic uncertainty and the value of the stock market emphasized by Lettau et al. (2008). Figure 9 presents analogous plots for all countries in our sample. This extends the results of Lettau et al. (2004) by including more countries and longer sample periods for several countries. The comovement of economic uncertainty and stock prices varies across countries and time. It is not very strong for most countries before 1970, but is stronger after this.

The third panel of Table 7 presents results on the predictability of consumption growth. The price-dividend ratio on stocks has little predictive power for consumption growth both in the U.S. or in the median country in our sample. These results extends earlier work by Beeler and Campbell
(2012). Our estimated version of the long-run risks model generates more predictability of consumption growth than we see in the data. In the data, the regression coefficients and R-squared for these regressions are less than 0.05, while it is 0.29 in our baseline case and 0.18 in our simple model. Our estimated model generates a degree of predictability of consumption growth that is intermediate between that in Bansal and Yaron (2004) and Bansal et al. (2012).

6.4 The Volatility of Real Exchange Rates

An important finding from our empirical analysis is that there is a large amount of comovement of growth-rates and uncertainty across countries. This has important implications for real exchange rates. In a world with complete markets, the log change in the real exchange rate between two countries is

\[ \Delta e_t = m_t^* - m_t, \]  

where \( e_t \) denotes the log real exchange rate (home goods price of foreign goods), and \( m_t \) and \( m_t^* \) are the logarithm of the home and foreign stochastic discount factors, respectively. The annual standard deviation of changes in real exchange rates has been roughly 10% in the post-Bretton Woods period (see Table 8). However, Hansen and Jagannathan (1991) show that \( \sigma(M_t)R^f_t \geq E(R^e_t)/\sigma(R^e_t) \), where \( M_t \) is the level of the stochastic discount factor and \( R^e_t \) is the excess return on the stock market. From Table 5 we can see that \( R^f_t \simeq 1.01, E(R^e_t) \simeq 7\%, \) and \( \sigma(R^e_t) \simeq 18\% \), which implies \( \sigma(M_t) \geq 40\% \). Brandt, Cochrane, and Santa-Clara (2006) point out that this logic combined with equation (12) implies that either \( m_t \) and \( m_t^* \) are highly correlated—i.e., there is a high degree of international risk sharing—or exchange rates are not as volatile as the theory predicts. In addition, the low degree of comovement of consumption growth across countries at short horizons suggests that stochastic discount factors are not highly correlated. Colacito and Croce (2011) refer to this as the international equity premium puzzle.

The common components of growth-rates and uncertainty that we estimate have the potential to resolve this puzzle. They generate comovement in the stochastic discount factors across countries that is not evident from the short-run comovement of consumption growth. Table 8 presents the standard deviation implied by our estimated model of annual changes in the bilateral real exchange rate versus the United State for each country in our sample. The table also presents a counterfactual for this statistic based on the same simulated data from our estimated model but ignoring the correlation between the stochastic discount factors of each country and the United States that is implied by our model—i.e., simply adding the variances of the two stochastic discount factors and
taking a square root. We see that the presence of common long-run risk shocks in our model lowers
the volatility of the real exchange rate by roughly a factor of two relative to what it would be if the
stochastic discount factors were uncorrelated. Our model can therefore account for a large part of
the discrepancy between the observed volatility of the real exchange rate and the volatility implied
by a model in which marginal utility across countries is uncorrelated. Our results complement those
of Colacito and Croce (2011), who carry out a related exercise for the exchange rate of the U.S.
versus the U.K.

7 Conclusion

The long-run risks model is one of the leading frameworks of consumption-based asset pricing.
Because the model is difficult to estimate using macroeconomic data alone, most previous estimation
approaches use a combination of macroeconomic and asset price data to estimate the model. The
key difficulty is obtaining accurate estimates of persistent fluctuations in macroeconomic growth
and uncertainty using data from a single country. Our model of consumption dynamics allows for
country-specific variation in the average level of volatility across countries, but pools across countries
in estimating the persistence of growth-rate and uncertainty shocks as well as the volatility of shocks
to uncertainty. This allows us to estimate long-run risk parameters using macroeconomic data alone.
We can thereby avoid any reliance of our estimates on a particular asset pricing model, and the
concern that our estimates derive from a need to fit the asset pricing data.

Our estimates suggest that growth-rate and uncertainty shocks play an important role in as-
set pricing. We identify a large and persistent world growth-rate component and a less persistent
country-specific growth-rate process. Shocks to uncertainty are highly persistent and yield substan-
tial variation in uncertainty over time. With EZW preferences, current marginal utility depends
not only on current consumption growth but also on news about future growth and uncertainty.
With a CRRA\(>1\) and IES\(>1\), shocks that lower future expected growth or raise future economic
uncertainty raise current marginal utility and cause stock prices to fall. This generates a substantial
equity premium, high volatility of equity returns, predictability as well as a low and stable risk-free
rate.
A Model Estimation

We employ a Bayesian MCMC algorithm to estimate our model. More specifically, we employ a Metropolized Gibbs sampling algorithm to sample from the joint posterior distribution of the unknown parameters and variables conditional on the data. The full probability model we employ may be denoted by

\[ f(Y, X, \Theta) = f(Y, X|\Theta)f(\Theta), \]

where \( Y \in \{c_{i,t}, I_{i,t+1}^d\} \) is the set of observable variables for which we have data,

\[ X \in \{z_{i,t}, x_{i,t}, x_{W,t}, \sigma_{i,t+1}^2, \sigma_{W,t+1}^2\} \]

is the set of unobservable variables, and

\[ \Theta \in \{\rho, \rho_W, \gamma, \sigma_W^2, \sigma_{W,\omega}^2, \lambda, \lambda_W, \xi_i, \chi_i, \sigma_i^2, \sigma_{\nu,i}^2, \mu_i, \mu_d, \} \]

is the set of parameters. From a Bayesian perspective, there is no real importance to the distinction between \( X \) and \( \Theta \). The only important distinction is between variables that are observed and those that are not. The function \( f(Y, X|\Theta) \) is often referred to as the likelihood function of the model, while \( f(\Theta) \) is often referred to as the prior distribution. Both \( f(Y, X|\Theta) \) and \( f(\Theta) \) are fully specified in sections 3 and 4 of the paper. The likelihood function may be constructed by combining equations (2)-(4) and (8), the distributional assumptions for the shocks in these equations detailed in section 3 and the assumptions about the distributions of \( z_{i,t}, x_{i,t}, x_{W,t}, \sigma_{i,t}^2, \) and \( \sigma_{W,t} \) for the initial period for each country that are detailed in section 4. The prior distributions are described in detail in section 4.

The object of interest in our study is the distribution \( f(X, \Theta|Y) \), i.e., the joint distribution of the unobservables conditional on the observed values of the observables. For expositional simplicity, let \( \Phi = (X, \Theta) \). Using this notation, the object of interest is \( f(\Phi|Y) \). The Gibbs sampler algorithm produces a sample from the joint distribution by breaking the vector of unknown variables into subsets and sampling each subvector sequentially conditional on the value of all the other unknown variables (see, e.g., Gelman et al., 2004, and Geweke, 2005). In our case we implement the Gibbs sampler as follows.

1. We derive the conditional distribution of each element of \( \Phi \) conditional on all the other elements and conditional on the observables. For the \( i \)th element of \( \Phi \), we can denote this conditional distribution as \( f(\Phi_i|\Phi_{-i}, Y) \), where \( \Phi_i \) denotes the \( i \)th element of \( \Phi \) and \( \Phi_{-i} \) denotes all but
the $i$th element of $\Phi$. In most cases, $f(\Phi_i | \Phi_{-i}, Y)$ are common distributions such as normal distributions or gamma distributions for which samples can be drawn in a computationally efficient manner. In cases where the Gibbs sampler cannot be applied, we use the Metropolis algorithm to sample values of $f(\Phi_i | \Phi_{-i}, Y)$.

2. We propose initial values for all the unknown variables $\Phi$. Let $\Phi^0$ denote these initial values.

3. We cycle through $\Phi$ sampling $\Phi^t_i$ from the distribution $f(\Phi_i | \Phi_{-i}^{t-1}, Y)$ where

$$\Phi_{-i}^{t-1} = (\Phi_1', ..., \Phi_{i-1}', \Phi_{i+1}', ..., \Phi_d')$$

and $d$ denotes the number of elements in $\Phi$. At the end of each cycle, we have a new draw $\Phi^t$. We repeat this step $N$ times to get a sample of $N$ draws for $\Phi$.

4. It has been shown that samples drawn in this way converge to the distribution $f(\Phi | Y)$ under very general conditions (see, e.g., Geweke, 2005). We assess convergence and throw away an appropriate burn-in sample.

In practice, we run four such “chains” starting two from one set of initial values and two from another set of initial values. We choose starting values that are far apart in the following way: For one chain, we set the initial values of $x_{i,t} = 0$ for all $i$ and $t$. For the other chain, we set the initial values of $x_{i,t} = \Delta c_{i,t}$ for all $i$ and $t$.

Given a sample from the joint distribution $f(\Phi | Y)$ of the unobserved variables conditional on the observed data, we can calculate any statistic of interest that involves $\Phi$. For example, we can calculate the mean of any element of $\Phi$ by calculating the sample analogue of the integral

$$\int \Phi_i f(\Phi_i | \Phi_{-i}^{t-1}, Y) d\Phi_i.$$  

---

29 The Metropolis algorithm samples a proposal $\Phi_i^*$ from a proposal distribution $J_i(\Phi_i^* | \Phi_{-i}^{t-1})$. This proposal distribution must be symmetric, i.e., $J_i(x_a | x_b) = J_i(x_b | x_a)$. The proposal is accepted with probability $\min(r, 1)$ where $r = f(\Phi_i^* | \Phi_{-i}, Y) / f(\Phi_i^{t-1} | \Phi_{-i}, Y)$. If the proposal is accepted, $\Phi_i^t = \Phi_i^*$. Otherwise $\Phi_i^t = \Phi_i^{t-1}$. Using the Metropolis algorithm to sample from $f(\Phi_i | \Phi_{-i}, Y)$ is much less efficient than the standard algorithms used to sample from known distributions such as the normal distribution in most software packages. Intuitively, this is because it is difficult to come up with an efficient proposal distribution. The proposal distribution we use is a normal distribution centered at $\Phi_i^{t-1}$.  

---

22
B  Variance Ratios

Variance ratios are a simple tool to quantify the persistence of shocks to aggregate consumption (Cochrane, 1988). The $k$-period variance ratio for consumption growth is defined as the ratio of the variance of $k$-period consumption growth and 1-period consumption growth divided by $k$:

$$VR_{i,k} = \frac{1}{k} \frac{\text{var} \left( \sum_{j=0}^{k-1} \Delta c_{i,t-j} \right)}{\text{var}(\Delta c_{i,t})}. \tag{13}$$

The intuition for this statistic comes from the fact that for a simple random-walk process $\text{var}(c_{i,t} - c_{i,t-k})$ is equal to $k$ times $\text{var}(c_{i,t} - c_{i,t-1})$, implying that the variance ratio for such a process is equal to one for all $k$. For a trend-stationary process, the variance ratio is less than one and falls toward zero as $k$ increases. However, for a process that has persistent growth-rate shocks—i.e., positively autocorrelated growth rates—the variance ratio is larger than one.

Bansal and Yaron (2004) introduce a variance ratio statistic for assessing the persistence of shocks to volatility. They first compute the innovations to consumption growth $u_{i,t}$ as the residuals from an AR(5) regression and use the absolute value of these innovations $|u_{i,t}|$ as a measure of realized volatility of consumption growth. They then construct variance ratios for $|u_{i,t}|$,

$$VR^u_{i,k} = \frac{1}{k} \frac{\text{var} \left( \sum_{j=0}^{k-1} |u_{i,t-j}| \right)}{\text{var}(|u_{i,t}|)}. \tag{14}$$

This statistic provides a rough measure of the persistence of stochastic volatility. As with the variance ratio for consumption growth, if this variance ratio is above one, it indicates that uncertainty shocks have persistent effects on volatility—i.e., high volatility periods are “bunched together” leading to a high value of the variance in the numerator.

The table reports prior and posterior means of the parameters with prior and posterior standard deviations in parentheses. The "Baseline" case is for our full model estimated on data from 1890-2009. The "Simple Model" case is for our simple model estimated on data from 1890-2009. The "Post-WWII" case is for our full model estimated on data from 1950-2009. "Median" refers to the median country. In other words, we report the value of each statistic - both means and standard deviations - for the country that has the median value of that statistic.
The table reports autocorrelations, cross-country correlations and variance ratios for the real-world data and simulated data from the model (excluding disasters in both cases). The first row presents the autocorrelation of one year consumption growth. The second through sixth rows present the autocorrelation of two year through five year and ten year consumption growth. The next three rows present cross-country correlations of one, five and ten year consumption growth. The last two rows present the fifteen year variance ratio of consumption growth and the fifteen year variance ratio of the realized volatility of consumption growth. For the cross-country correlations, the median country results are the median of the 120 cross-country correlations across our 16 countries. For the results based on data from the model, we simulate 500 datasets from the model of the same size as the actual data and calculate all statistics for each and report the median across samples along with the 5% and 95% quantiles for each statistic. For the median country, we report the value of each statistic - median, 5%, 95% quantiles - for the country that has the median value of that statistic.

Columns labeled as "Median" report the result for the median country for each statistic. Columns labeled as "U.S." report these statistics for the United States. For the model, we report the value of these statistics from a sample of length 1 million years. For the statistics we report are the unconditional average of the level of the ex-post real net return in percentage points (i.e., multiplier by 100). R_m denotes the return on equity (the market), while R_f denotes the return on a short term nominal government bond (risk-free rate). The last three rows report statistics for the logarithm of the price-dividend ratio on equity. These results are for a CRRA = 6.5, IES = 1.5 and subjective discount factor of β = 0.99.

The table presents asset pricing statistics based on simulated data from our model as well as historical data from the world. The "Constant Volatility" model is version of the full model where we "turn off" the stochastic volatility by setting the volatility of the uncertainty shocks $\omega$ and $\omega W$ to zero but keep other parameters at their estimated values for the full model. For the "Mehra-Prescott" model we "turn off" both the stochastic volatility and the growth-rate shocks and then we recalibrate the random-walk shocks based on the volatility of $z_t$ in the full model. These results are for a CRRA = 6.5, IES = 1.5 and subjective discount factor of $\beta = 0.99$.

</table>

The table reports results from regressions of excess returns, consumption growth and realized volatility at a 1, 3 and 5 year horizon on the price-dividend ratio. Our measure of realized volatility is the absolute value of the residual from an AR(1) model for consumption growth. The first two columns report results using data from our 16 country sample and the U.S., respectively. The first column is the median across countries of the statistic in question. The next two columns report results from our model. The last two columns report results for the models of Bansal and Yaron (2004) and Bansal, Kiku and Yaron (2012). The results for the Bansal-Yaron model are taken from Beeler and Campbell (2009). We use the end of year convention for the timing of consumption.

</table>

The table presents the standard deviation of the log change in the real exchange rate of each country with the U.S.
The table presents our estimates of the posterior mean and standard deviation of the country-specific parameters in our full model.

</table>

Columns labeled as "Median" report the result for the median country for each statistic. Columns labeled as "U.S." report these statistics for the United States. For the model, we report the value of these statistics from a sample of length 1 million years. For returns the statistics we report are the unconditional average of the level of the ex-post real net return in percentage points (i.e., multiplier by 100). $R_m$ denotes the return on equity (the market), while $R_f$ denotes the return on a short term nominal government bond (risk-free rate). The last three rows report statistics for the logarithm of the price-dividend ratio on equity. These results are for a CRRA = 6.5, IES = 1.5 and subjective discount factor of $\beta = 0.99$.
