The Modern Wholesaler: Global Sourcing, Domestic Distribution, and Scale Economies

Aug 2018

Abstract

Nearly half of all transactions in the $6 trillion market for manufactured goods in the United States were intermediated by wholesalers in 2012, up from 32 percent in 1992. Seventy percent of this increase is due to the growth of “superstar” firms - the largest one percent of wholesalers. Structural estimates based on detailed administrative data show that the rise of the largest wholesalers was driven by an intuitive linkage between their sourcing of goods from abroad and an expansion of their domestic distribution network to reach more buyers. Both elements require scale economies and lead to increased wholesaler market shares and markups. Counterfactual analysis shows that despite increases in wholesaler market power, intermediated international trade has two benefits for buyers: directly through buyers’ valuation of globally sourced products, and indirectly through the passed-through benefits of wholesaler economies of scale and increased quality.

Keywords: market power, intermediation, wholesale trade, geographic differentiation, imports, sourcing, returns to scale

*I am indebted to my advisors Pinelopi Goldberg and Costas Arkolakis and my dissertation committee members Steve Berry and Peter Schott. I thank Nina Pavnick, Treb Allen, Joe Shapiro, Phil Haile, Samuel Kortum, and Lorenzo Caliendo for additional valuable comments. This work was further guided by feedback from Andrew Bernard, Mitsuru Igami, David Atkin, Dan Ackerberg, Fiona Scott Morton, Giovanni Maggi, Kevin Williams, Meredith Startz, Jeff Weaver, Marcelo Sant’Anna, Jesse Burkhardt, Giovanni Compiani and Ana Reynoso as well as seminar participants and discussants at Yale, Harvard Business School, UCLA, Chicago Booth, Columbia, Dartmouth, Georgetown, UC Santa Cruz, Penn State, UBC, Federal Statistical RDC Conference, 2016 Econcon, 2016 WEAI, 2017 DC IO Day, 2017 EITI, and 2018 EITI meetings. This work was partially conducted with the support of the Carl Arvid Anderson Prize Fellowship. Jonathan Fisher and Shirley Liu at the New York Census Research Data Center and Stephanie Bailey at the Yale Federal Statistical Research Data Center provided valuable data support. Peter Schott additionally provided concordance tables for international trade data. Any opinions and conclusions expressed are those of the author and do not necessarily represent the views of the U.S. Census Bureau. All results have been reviewed to ensure that no confidential information is disclosed. All errors are mine.
1 Introduction

Newly developed scale economies can quickly change a competitive marketplace. A large fixed investment may allow the largest firms to develop better products and reduce marginal costs. A new warehouse and logistic network, made useful by a globalized supply chain and coordinated by newly developed IT systems, can cost billions to develop and maintain. But these fixed costs may realize lowered operating costs. A firm that develops such a network can easily dominate their competitors, simultaneously increasing markups, growing market shares through scale, and providing a more valuable service or product to their customers.

I study the interaction of global sourcing and domestic distribution networks in the context of the business-to-business wholesale industry. Wholesalers are middlemen that sell almost exclusively to other businesses. With advances in electronic communication technologies and falling trade costs, we imagine that the economy is moving to a frictionless state where buyers and sellers seamlessly connect, bypassing such middlemen. However, in the distribution of manufactured goods, the opposite has occurred: using rich United States administrative data over the last two decades, I show that these wholesale middlemen are more important than ever, doubling the value of distributed goods to three trillion dollars, expanding their distribution networks, and connecting domestic buyers to international markets.

I make two principal contributions. First, I document the growing importance of wholesalers in distributing imported and domestic goods within the United States and show that this increase is driven by the intensive margin, with the largest wholesalers increasing in size. Second, I use a structural model to rationalize these trends, conduct counterfactuals to quantify their market consequences, and evaluate the role of wholesalers in globalization. I show that trade allows for the endogenous entry of higher quality wholesalers, who simultaneously exploit scale, gain market power, distribute more globally-sourced varieties, and charge higher markups.

De Loecker and Van Biesebroeck (2016), summarizing recent work at the intersection of international trade and industrial organization, find that trade studies largely ignore the distortionary effects of market power following the introduction or expansion of trade and simultaneously downplay the importance of intra-national or localized competition between firms. \(^2\) This paper explicitly corrects for these gaps within wholesale trade. \(^3\) These results also illustrate an important linkage between international trade and market concentration. Academic and public discourse (The Economist, 2016; Autor et al., 2017) has highlighted both increasing market power and market concentration across the economy as areas of general interest. Possible explanations for this linkage include technological innovation, firm consolidation, and the influence of large, diversified shareholders. \(^4\) This paper introduces another mechanism: the increasing returns to scale introduced by the fixed costs of international trade and their interaction with domestic

\(^1\) This notion of scale economies entangles both traditionally defined scale and scope economies, where a large fixed cost is paid to realize a given marginal cost.

\(^2\) They note that “...the interaction between efficiency and market power tends to be ignored. This is problematic as firms can use higher quality (imported) inputs or favorable locations to differentiate themselves and increase or gain market power” and “A final research avenue we believe to be promising is to study the distinction between local and global competition.”

\(^3\) Feenstra and Weinstein (2017) allows for variable markups in manufacturing, but they largely stem from variation on firm-level demand elasticity, not through oligopoly and competition.

\(^4\) For example see Autor et al. (2017); Azar et al. (2016); De Loecker and Eeckhout (2017); Gutiérrez and Philippon (2017); Barkai (2016).
investments, dovetailing with markup evidence from De Loecker et al. (2016) and holding true to the spirit of trade models since Krugman (1980). Berry (2017) notes that the vast majority of work concerning aggregate competition levels avoid using the tools of modern industrial organization and applied microeconomics, reverting to either macroeconomic models or cross-industry regressions. This paper paper scales up the methods from standard industrial organization to a large sector, allowing for a model based decomposition of the effects of market concentration, in addition to the ability to conduct counterfactuals.

This paper unfolds in four parts. First, it uses detailed micro data to characterize the nature and growth of the U.S. wholesale sector. In 2012, independent wholesale businesses accounted for nearly 50% of sales to downstream buyers in the $6 trillion manufactured good market. This figure is driven by wholesaler growth, as transactions intermediated by wholesalers have grown faster than the overall market. From 1997 to 2007, the share of transactions intermediated by wholesalers increased 34%, with internationally sourced varieties accounting for half of this gain. This growth is entirely driven by the intensive margin, through the increased market share of the largest 1% of wholesalers. This expansion corresponds to these large wholesalers increasing the number of imported varieties by 56% and domestic distribution warehouses by 70%. In contrast, the median wholesaler rarely imported and did not expand their distribution network.

Second, this paper structurally estimates downstream buyer demand for wholesalers, extending McFadden (1973) and Hausman, Leonard and McFadden (1995) to decompose wholesaling’s benefits. Cost-minimizing downstream buyers either indirectly source intermediate goods from a wholesaler at a markup or directly source from a manufacturer and pay a large fixed cost. Heterogeneous, geographically dispersed downstream buyers first choose how much to buy and then choose their optimal sourcing strategy from a set of wholesalers. Differentiated wholesalers compete horizontally (types of distributed varieties), vertically (distribution quality), and spatially (geographic reach). Demand is identified through geographic proxies for cost shifters, accounting markup data, and variation in choice sets across geography.

Third, the model endogenizes the prices, attributes, and entry decision of wholesalers. I recover wholesaler marginal costs and operating profits from a price-setting supply system with oligopolistic competitors. Subsequently, I consider the entry costs of wholesalers, who make increasingly large fixed investments in (a) more efficiently sourcing products from far-flung foreign factories and (b) setting up domestic facilities to redistribute these products across the nation. These fixed costs are estimated using equilibrium conditions that rationalize both the number and type of operating firms.

Fourth, I quantify the gains from wholesaling by running counterfactuals under the fully estimated model. In the principal scenario, indirect sourcing via wholesalers for international products is restricted to recover the downstream buyer gains from wholesaler-intermediated international trade. Through complementarities in investment, increases in international trade positively interact with the size of a wholesaler’s domestic distribution network, compounding and nearly doubling the gain in aggregate buyer surplus. Specifically, the expansion of whole-

---

5 Other structural work with intermediates, such as Bar-Isaac and Gavazza (2015); Salz (2015), do not endogenize all of these decisions.

6 Unlike Petrin (2002), I refrain from directly considering welfare. Downstream buyers in this model are firms, not consumers. Second, this is not a general equilibrium model - I do not consider who the underlying owners of firms are, nor do I directly model manufacturing firms. Similarly, I abstract from issues of double marginalization.
salers into international trade in 2007 saved downstream buyers 11-12% in procurement costs as a percentage of purchase value ($540-580 billion). However, due to large fixed costs, the largest 1% of wholesalers are able to increase their overall market share by 30% and their operating profits by 60%.

There is an extensive theoretical literature on intermediation. Early work by Rubinstein and Wolinsky (1987) endows intermediaries with a special matching ability to connect buyers and sellers. As summarized by Spulber (1999), these intermediaries can satisfy a variety of purposes: providing liquidity and facilitating transactions, guaranteeing quality and monitoring, market-making by setting prices, and matching buyers with sellers. This paper empirically addresses these purposes, combining the costs of facilitating transactions and ensuring quality as fixed costs that must be paid by a wholesaler and which allow a wholesaler to charge markups.\(^7\)

The comprehensive empirical study of wholesaler markets is sparse. In industrial organization, recent papers by Salz (2015) and Gavazza (2011) consider informational intermediaries and brokers, as opposed to physical good wholesalers. These papers address Spulber’s last criteria, with wholesalers reducing the cost of matching buyers and sellers. This paper adds to the literature by endogenizing the entry of middlemen and allows for endogenous middlemen quality and markups.\(^8\)

In international trade, their presence has been well documented by Feenstra and Hanson (2004), Bernard, Jensen, Redding and Schott (2010), Bernard, Grazzi and Tomasi (2011), and Abel-Koch (2013), who all find the rich and enduring presence of such intermediaries. A set of papers places wholesale exporters within a general equilibrium framework and validate a series of cross-sectional predictions (Akerman, 2010; Ahn, Khandelwal and Wei, 2011; Felbermayr and Jung, 2011; Tang and Zhang, 2012; Crozet, Lalanne and Poncet, 2013). Gopinath, Gourinchas, Hsieh and Li (2011) and Atkin and Donaldson (2012) study the role of prices and pass-through, but do not consider the exact mechanisms that lead to pass-through. Bernard and Fort (2015) and Bernard, Smeets and Warzynski (2016) explore the emergence of factory-less good producers, which account for a portion of the wholesale industry. These papers all point to the importance of wholesalers, but consider their market structure as a black box.

The remainder of the paper is as follows. Section 2 outlines the wholesaling industry and provides a case study. Section 3 describes the model. Section 4 explains identification and estimation. Sections 5, 6, and 7 summarize the estimation results, decompose results, and compute counterfactuals. Section 8 discusses alternative and complementary explanations and Section 9 concludes.

2 Data and Industry Facts

Market intermediaries come in many varieties and forms: some act as market-makers and others act as distributors. I focus on the latter, which are called wholesalers and defined by the US Census as: on manufacturer prices.

\(^7\)Within international trade, Rauch and Watson (2004), Petropoulou (2008), Antrás and Costinot (2011), and Krishna and Sheveleva (2014) consider alternative theoretical models for the gains from intermediation.

\(^8\)Papers such as Villas-Boas and Hellerstein (2006), Villas-Boas (2007), Nakamura and Zerom (2010), and Goldberg and Hellerstein (2013), consider retailers in a similar fashion to wholesalers.
... an intermediate step in the distribution of merchandise. Wholesalers are organized to sell or arrange the purchase or sale of (a) goods for resale (i.e., goods sold to other wholesalers or retailers), (b) capital or durable non-consumer goods, and (c) raw and intermediate materials and supplies used in production.\footnote{For full description see Appendix A.}

Within this category, I consider merchant wholesalers. These firms are independent of manufacturers and physically maintain possession of goods between manufacturer and downstream buyer.\footnote{I specifically exclude own-brand marketers to separate firms that design, market and sell, but that do not manufacture their products. In these cases, there is simply a division of the surplus problem that occurs between the design studios and the manufacturing arm; and are just two divisions of the same firm.} In order to gain tractability, I present a simplified notion of the wholesale industry. End users can either buy directly from a manufacturer or from a wholesaler. Wholesalers source goods from a set of available manufacturers for a particular downstream user and then resell at an endogenously determined price.\footnote{As is the case for the vast majority of economic studies, I simplify many aspects of the wholesale industry to balance realism with parsimony and tractability. In reality, there are many more business structures, ranging from exclusive contracts to brokers. For example, I implicitly incorporate exclusive contracts into my model through the unobservable term $\xi$ in Section 3. As for brokers, I veer on the conservative side and consider sales aided by such agents as direct sales from manufacturers to downstream users and thus part of the outside option in equation (1) in Section 3.} This process is illustrated first by an industrial case-study and then summarized using comprehensive administrative data. Both the case-study and summary data provide salient details that will be incorporated into the model and estimation.

\subsection*{2.1 Wholesaler Case Study}

Consider the case of specialty industrial chemicals. This sector grew 28\% between 2008 and 2013; however, the share of products distributed by independent wholesalers increased 37\%. Industry reports (Elser et al., 2010; Jung et al., 2013, 2014) highlight two types of observations, (a) why particular downstream buyers contract with wholesalers instead of manufacturers and (b) what differentiates successful wholesalers from unsuccessful wholesalers.

Downstream buyers face heterogenous barriers to directly purchasing chemicals from a manufacturer. According to a 2009 Boston Consulting Group survey, 80\% of downstream buyers with purchases valued under €100,000 sourced goods indirectly through wholesalers, while larger purchasers nearly always sourced directly from a manufacturer. Downstream buyers value traditional distributor attributes such price, quality, and globally sourced varieties and are differentiated on two characteristics, their size and geographic location.\footnote{Smaller downstream buyers “typically lack the critical mass needed to tap into low-cost sources for chemicals from China, Eastern Europe, or the Middle East.” In addition, these downstream buyers not only value price, product quality, and technical support, they prize flexibility and speed of delivery, which are highly correlated with geographic proximity.}

In the industrial chemical market, wholesaler distributors perform three functions as they (a) source products from multiple manufacturers, (b) repackage these products, and (c) ship these products to downstream buyers. While the global market for distributors is still fragmented, it is experiencing rapid consolidation, with the three largest companies in 2011 holding 39\% of the North American market. In particular, the largest distributors have grown faster than the market, driven by both organic expansion and market acquisitions. In contrast, smaller

Notes: Quantities in producer prices. Exports and Imports assumed in producer prices unless conducted by a wholesaler, whereby prices are then adjusted using a wholesaler-specific margin. Data on 2012 derived from aggregate Census data.

Distributors face increasing fixed costs, as they try to “combine global reach with strong local presence.”

Consider one of the large speciality chemical distributors, Univar. Univar is a large industrial chemical wholesaler with North American shipments of approximately $10.4 billion in 2014. The company was formed in 1928, increasing its distribution footprint through acquisitions and expansions. Today, it sources 30,000 varieties of chemicals and plastics from over 8,000 internationally distributed suppliers. Univar uses its 8,000 employees to run a distribution network spanning hundreds of locations to supply 111,000 buyers. 13

Downstream buyers may need any of a variety of chemicals, and they may source these chemicals directly from manufacturers such as DuPoint and BASF or indirectly through Univar. However, BASF and DuPont facilities may be located in distant locations and only stock their own product lines. Instead of individually sourcing chemicals, downstream buyers may pay a markup and have Univar do this for them, and have Univar source the shipments from each respective chemical manufacturer and reship them to a convenient loading bay. This tradeoff between convenience and price is one of the central dynamics underpinning the wholesale industry. This also offers insight into why the wholesale industry may be gaining market share, as the proliferation of new global sources and varieties may make it harder to optimally source intermediate products for production. 14

2.2 Data Description

I bring together a variety of censuses and surveys conducted by the United States Census Bureau, Department of Transportation, and Department of Homeland Security covering international

13 Univar’s business plan is summarized in a slide presented as Appendix Figure 7.

14 Feenstra and Weinstein (2017) show that the number of manufactured varieties in the US has increased over time due to global trade.

These databases are linked together every 5-years at the firm level and provide at the aggregate level the share of goods distributed by a wholesaler in approximately 60 distinct product categories, corresponding to North American Industry Classification System (NAICS) 5-digit sectors. I will treat each of these product categories as an independent market. I focus on wholesalers independent of manufacturing establishments and collect details on each wholesaler’s aggregate sales, physical locations, operating expenses, and the extent of international trade. Additionally survey data provides statistics on the distribution of the origin, destination, and size of shipments across wholesalers and manufacturers. One limitation of the shipment data is the lack of information on the identity of downstream buyers; I only know the quantity purchased and their geographic location. This will have serious implications on my modeling choices. The model will have to provide a way of understanding possible unobserved heterogeneity in buyers - especially in the tradeoff between foreign and domestic products as well as between one-off and repeat buyers (who may require a broader set of available products). Certain industries related to petroleum, alcohol, and tobacco are removed due to data issues. I focus on data from 1997-2002, as disaggregated firm-level data from 1992 and 2012 are not comparable due to industry reclassifications.

While there is wide heterogeneity across NAICS 5-digit sectors. This project explicitly generalizes away from such differences, focusing on average changes across time. These are the changes that are relevant to the larger picture and have implications for markups and prices at the economy-wide level. Additionally, individual market data is restricted by Census disclosure procedures, as market-level data on highly concentrated industries cannot be publicly released.

This analysis is based on quantities in terms of producer prices. There are multiple reasons for doing this, and the first is due to the availability of data. While certain small industries produce quantity data, they form only a small portion of the overall goods economy. Secondly, when available, physical quantity data rarely includes information on quality and cannot be easily compared across closely related sub-sectors. Third, in the United States, the Robinson-Patman Act of 1936 (also known as the Anti-Price Discrimination Act) prevents price discrimination to similar downstream buyers. Thus, an upstream manufacturer cannot charge a wholesale distributor different prices from a downstream buyer, conditional on purchase type.

2.3 Descriptive Results

While the previous case study considers the distribution of goods within one sector, US Census micro-data shows similar trends and relationships across wholesale sectors. This data shows the rise of wholesalers both in aggregate and within intermediate goods sectors over time. It also highlights a series of facts that inform my modeling decisions. Within wholesaling, the

Notes: Varieties measured at the HS-8 level.

largest wholesalers have been gaining market share while (a) expanding globalized sourcing and (b) increasing the number of domestic distribution outlets. This coincides with wholesalers increasing operating markups, while simultaneously decreasing operating costs. Wholesalers serve geographically proximate buyers that request low-valued shipments, even though these customers have been requesting ever-larger shipments over time. I elaborate on these descriptive facts below.

**Fact 1** The share of manufactured product distributed by wholesalers has increased over time, particularly for imported goods.

Manufactured products can be shipped via one of two modes, (a) directly from the manufacturer to a downstream user or (b) indirectly through a wholesaler. Table 1 shows the aggregate share of domestic absorption of manufactured goods distributed by all wholesalers from 1992 to 2007. In 1992, wholesalers accounted for the distribution of just 32% of all manufactured goods. In contrast, in 2007, wholesalers accounted for 42.5% of all shipments to downstream buyers.

Such aggregate trends may be caused by compositional shifts across product types. In particular, products such as chemicals with large wholesale shares have increased in importance over time. A regression with appropriate controls accounts for this possibility. I regress the wholesaler
market share by product type\textsuperscript{18} with yearly and product type fixed effects for 1997, 2002 and 2007 across approximately 400 product types.

\[
\text{wholesale share}_{i,t} = 0.33 + 0.05 \times I_{2002} + 0.09 \times I_{2007} + \beta_i + \epsilon_{it}
\]

\[r^2 = 0.92\]

observations \approx 1200

Regressors \(I_t\) are dummy indicators by years, and \(I_i\) are indicators for product types. These results imply that wholesale shares increased on average by 5 percentage points from 1997 to 2002 and another 4 percentage points from 2002 to 2007, broadly reflecting the change in aggregate market shares.

Simultaneously, the proportion of goods distributed by wholesalers and acquired abroad has similarly increased. The trend is highlighted in Table 1. In 1997, such products accounted for 18\% of wholesaler sales and 6\% of all domestic purchases. By 2007, these products made up 32\% of wholesalers sales and 10.1\% of all domestic purchases.

**Fact 2** *Wholesalers are becoming more heterogeneous, with the largest wholesalers increasing market shares and importing a larger share of their products.*

Most work on intermediates treat wholesalers in this sector as identical within a market. As shown in Tables 2 and 1, there is incredible heterogeneity in wholesalers, both inter-temporally and cross-sectionally.\textsuperscript{19} Over just 10 years, the average wholesaler has nearly doubled real sales and become 35\% more likely to source products internationally, from where they import 68\% more varieties at the Harmonized System 8-digit category level. On average, these wholesalers increased the number of domestic distribution centers by 8\%.

Changes across time provide insight into why certain wholesalers are increasing their market shares. The average wholesaler in the 99.5\textsuperscript{th} percentile of a sector by sales controls nearly 1\% of the national market, a share hundreds of times larger than the smallest wholesaler. Considering geographic and quantity market segmentation, this can easily translate to large effective market shares in particular segments and thus the ability to exert market power. Additionally, these large wholesalers are differentiated in many other ways; compared to a median wholesaler, they are 4 times more likely to import goods from abroad and have nearly 20 times more domestic distribution centers.

Even starker are the inter-temporal trends across wholesalers. The 99.5\textsuperscript{th} percentile of wholesalers increased their aggregate market shares 50\%, while increasing the average number of imported product varieties from 140 to 210 and the number of distribution locations by 68\%. In contrast, the median wholesaler’s market share stayed constant, with no measurable change in the number of domestic distribution centers. Substantial heterogeneity may imply that larger wholesalers make strategic competitive decisions, while the smallest wholesalers are too small to exert market power.

\textsuperscript{18}I used the 5-digit commodity code from the Commodity Flow Survey. Similar results hold at higher levels of aggregation.

\textsuperscript{19}Detailed statistics are available in Appendix Tables A1 - A3.

Notes: Each cell represents the percent of shipment by overall type of shipper within a geographic scope.

Fact 3 Average wholesaler markups are increasing, even though reported operating costs are falling.

In 1997, aggregating across industries, wholesalers charged downstream customers $1.32 for $1.00 worth of manufactured goods. In 2007, wholesalers charged $1.31 for the same service. However, wholesaler reported operating costs fell substantially from $0.21 to $0.16, leading to implied aggregate markup increases from 9.3% to 12.7%, after accounting for the cost of goods sold. This aggregate trend further masks average price increases across industries and is confirmed at the industry level. Regressing accounting profits on year and industry fixed effects and allowing for industry-clustered standard errors:

\[
\log(\text{accounting profit rate}_{i,t}) = -2.78 + .31 \times I_{2002} + .48 \times I_{2007} + \bar{\beta}_t + \epsilon_{it}
\]

\[
r^2 = .85
\]

Compared to 1997, wholesale industry-level accounting profit rates are 30 percent higher in 2002 and 48 percent larger in 2007.\(^2^1\)

These increased markups are consistent with increasing concentration, but not immediately rationalized by the increase in total wholesaler market share. To increase market shares, there must be improvements in wholesaler technology, products, or reach, to compensate downstream firms. Having focused primarily on the upstream aspect of the data, I shift to describing the nature and types of buyers in my model.

Fact 4 Wholesalers, in contrast with manufacturers, predominantly ship products to nearby destinations.

Wholesalers specialize in local availability: they form a middle link in getting goods from a factory to retailers and downstream producers. This fact is illustrated in Table 3. For example, a wholesaler is nearly 70% more likely than a manufacturer to conduct a shipment within the same state. The preponderance of local shipments allows wholesalers with distribution centers in relatively isolated locations to exert local market power.

Fact 5 Smaller purchases predominantly originate with wholesalers, instead of manufacturers.

---

\(^2^0\) Computed at (revenue - operating expenses - cost of goods sold)/revenue after inventory adjustment at the 5-digit NAICS industry level.

\(^2^1\) Results are robust to running this exercise in levels. Industry profits are increase from 6.6% to 9.11% in 2002 and 10.5% in 2007.

</table>

**Notes:** Figures in real 2007 dollars. Quantities equal revenues in producer prices. First two columns each sum to 1. Each row in the last two columns sum to 1.

Downstream wholesaler shipments are of much smaller value than manufacturer shipments. Table 4 shows that shipments worth $1000 or less in producer prices account for 15% of total wholesaler shipments, but only 4% of manufacturer shipments. In contrast, shipments of over $1,000,000 account for only 1% of wholesaler shipments, but 10% of manufacturer shipments. Certain wholesalers may exert market power in small shipments, even if they exhibit smaller overall market shares. In Appendix A.5, I note that that purchase sizes are slightly increasing over time, implying that a shift of buyer types does not explain the movement to wholesalers.

## 3 Model

To compute downstream gains from wholesaling, I construct a demand system paired with a wholesaler supply and entry model. Estimates from the demand model can determine downstream valuations for prices and various wholesaler attributes such as international sourcing. The supply model considers the relationship of prices with underlying marginal costs and market competition. These two stages will help determine the underlying forces driving the increase in wholesaler market shares. Finally, the wholesaler market entry game will produce entry cost estimates for counterfactual estimation.

I estimate a series of static games at 5-year intervals using detailed data from 1997, 2002, and 2007 - when industry codes retain compatibility. Each firm makes a one-time decision to enter the market. This paper does not reflect on the identity of the firms, allowing for tractability without having to make restrictive assumptions of the number of entrants or the forward looking expectations of continuing firms.

### 3.1 Model Overview

There are four periods, \( t_1 - t_4 \). Periods \( t_1 - t_2 \) consider the decisions made by wholesalers. At \( t_1 \), wholesalers make market entry decisions and at \( t_2 \) wholesalers choose their prices. I will refer to stages \( t_1 \) and \( t_2 \) as *wholesaler entry* and *wholesaler pricing* respectively. Periods \( t_3 \) and \( t_4 \)
involve the decisions made by downstream buyers searching for suppliers. At period \( t_3 \), aggregate downstream demand is determined, and downstream buyers choose how much to buy. Finally at \( t_4 \), downstream buyers choose between indirectly sourcing through wholesalers or directly sourcing from upstream sources. I will call stages \( t_3 \) and \( t_4 \) \textit{market size} and \textit{downstream choice} respectively.

In a pre-period \( t_0 \), the characteristics of upstream producers and manufacturers are made, they determine what to produce and how much to charge for it. This empirical strategy will take decisions made at \( t_0 \) as exogenous and open for future analysis; the focus will be on estimating and solving stages \( t_1 \) through \( t_4 \).

To aid in identification, wholesalers’ entry and investment choices are consolidated in \( t_1 \). Wholesalers first decide to enter a market and choose their market position. In practice this means that wholesalers choose both their geographic locations and how intensely to participate in global sourcing. Wholesalers pay a fixed cost, conditional on their choices, and receive the ability to consolidate and ship manufacturer goods. Following this stage, wholesalers receive marginal cost and product quality shocks.

At the pricing stage \( t_2 \), wholesalers take into account expected buyer characteristics and their own attributes to choose a price. I model this choice in terms of Bertrand competition with differentiated products for both tractability and realism. Wholesaling is an industry where capacity constraints are relatively easy to solve, even in the short run. Trucks and warehouses can be quickly and easily leased on short notice, and inventory can be readily acquired from the upstream manufacturing sector. At this stage, wholesalers have rational expectations of downstream buyer demand.

Downstream purchase choices occur in two stages. At time \( t_3 \), the total market size is determined. Downstream buyers consider their expected procurement costs and decide whether to make purchases and if so, how much to purchase. In the real world, downstream firms make joint decisions on both the extensive and intensive margin of sourcing. This is a hard problem to solve, and the data lacks information on the extensive margin of buying. As such I wrap the decision of whether to buy and how much to buy (the intensive and extensive margins) together into period \( t_3 \). This stage substitutes for the role played by the outside option, to ‘not-buy’ in standard discrete choice models. For example, this might be realized as 300 buyers demanding 1,000,000 units of industrial chemicals in New York.

At \( t_4 \), each of these downstream buyers make a choice to either source indirectly from a particular wholesaler or directly from a manufacturer. Each individual downstream buyer realizes a wholesaler-specific preference shock and makes their purchasing decision. Demand is fully realized.
This model is solved through backward induction, focusing first on the two-stage demand system, then the pricing system, before concluding with the market entry step.

### 3.2 Stage 4: Choice of Downstream Buyer

At $t_4$, heterogenous downstream buyers choose an optimal source for a given purchase. These downstream buyers seek to minimize procurement costs. There are two main methods of sourcing a good, either directly from a manufacturer or indirectly through a wholesaler. A particular downstream buyer $i$, indexed by observable type $j$ can buy directly from a manufacturer or from a wholesaler $w \in W$ that sources products from origin country $o \in O$. Types $j \in J$ index purchases by their geographic location and quantity demanded. Denoting the cost of sourcing $q$ units of a good, a downstream firm can source from a manufacturer at cost $C_{i,j,m}$ or from a particular wholesale-origin combination at cost $C_{i,j,w,o}$:

\[
C_{i,j,m} = q_j \times F_m(q_j) \times \exp(\epsilon_{i,j,m})
\]
\[
C_{i,j,w,o} = q_j \times p_{w,o} \times \exp(X_{j,w,o} \beta) \times \exp(\epsilon_{i,j,w,o}), \forall w, o \in \{W \times O\}
\]

Direct sourcing from a manufacturer costs the number of units bought, the amortized per-unit fixed cost $F_m(q_j)$, and an unobserved direct-buy match value $\epsilon$. Indirect sourcing through a wholesaler forgoes the fixed cost, but incurs the wholesaler price $p_{w,o}$, the valuation of any observable wholesaler or buyer-specific attributes $X$, and an unobservable wholesaler-buyer match value $\epsilon$. A downstream firm minimizes their cost $C$:

\[
C_{i,j} = \min \{C_{i,j,m}, C_{i,j,w_1,o_1}, \ldots, C_{i,j,W,O}\}
\]

Normalizing the cost of sourcing directly from a manufacturer and taking natural logarithms produces a standard discrete choice problem:

\[
\arg\max_{w,o \in \{W \times O\}} \{0, \delta_{j,w,o} + \epsilon_{i,j,w,o} \ldots \delta_{j,W,O} + \epsilon_{i,j,W,O}\}.
\]

Wholesalers $w$ provide mean benefit $\delta_{j,w,o}$ to all buyers of type $j$ when selling products from origin $o$ and customer-specific deviation $\epsilon_{i,j,w,a}$. This $\epsilon$ is unobserved by the econometrician and can represent unmeasured variables, optimization errors, and unobserved preferences. The cost-minimization problem implies a linear functional form for $\delta$:

\[
\delta_{j,w,o} = \alpha^p \log p_{w,o} + \alpha^{l_{state}} l_{j,w,o} + \alpha^{l_{region}} l_{j,w,o} + \alpha^q \log q_j + a_{w,o} \alpha^a + \xi_{w,o}
\]

These preferences are a function of both wholesaler and buyer attributes. In particular, wholesaler price ($p_{w,o}$), wholesaler location ($l_{w,o}$), and observable wholesaler characteristics ($a_{w,o}$). The vector $a$ includes characteristics of the wholesaler, such as the number and variety of international sources, as well as market-level observables, which include market-year fixed effects as well as

\[\text{For more details of the downstream buyer’s cost minimization problem, see Appendix B.}\]

\[\text{Within each type } j, \text{ buyers are unobservable differentiated in two dimensions. First downstream buyers have unobserved preferences over the country origin of their product. Second, downstream buyers have unobserved preferences over wholesaler attributes.}\]
indicators for the source of the good and the location of the wholesaler. All these characteristics are endogenous, however they are determined earlier in the game, and are taken as fixed in this stage. There are two relevant observable buyer attributes: their location ($l_j$) and their purchase size ($q_j$). The residual $\xi_{w,o}$ denotes the unobserved quality of wholesaler $w$ selling products from $o$; it is realized between stages $t_1$ and $t_2$.

The indicator function $I_{l_j,w,o}$ captures the interaction of $l_j$ and $l_{w,o}$; $I_{l_j}^{state}$ equals one when the wholesaler and buyer are in the same state and $I_{l_j}^{region}$ equals one when the wholesaler and buyer are in the same Census region. The vector $\alpha = (\alpha_p, \alpha_l, \alpha_q, \alpha_a)$ captures buyer’s sensitivity to wholesaler prices, location choices, purchase quantities, and observable characteristics. The parameters $\alpha_p$ and $\alpha_q$ capture the trade-off between the variable cost of buying $q$ units at price $p$ from a wholesaler with the fixed cost of directly sourcing $q$ units of the good from the manufacturer.

Following McFadden (1980) and Bresnahan et al. (1997), I assume the distribution of the vector of $\epsilon$ for a given buyer $(i,j)$ is drawn from a “principals of differentiation” (PD) nested logit model. Unobserved differentiation in buyer preferences is over two dimensions. First buyers have unknown preferences between products sourced domestically and from abroad (dimension $o \in O$). Second, buyers also have preferences over wholesaler attributes. They may prefer a wholesaler with a broad product line, containing both domestically and internationally sourced products (dimension $n \in N$). This relaxes the independence of irrelevant alternatives and allow for purchases within categories to be correlated. Thus, if a wholesaler that sources internationally increases its prices, downstream buyers will likely switch to another wholesaler that also sources internationally rather than a wholesaler that only sources domestically.

In this application there are three possible product origins $o$: those sourced domestically, those sourced internationally from high income countries, and those sourced internationally from low income countries. This is a generalization of the Armington assumption that there is imperfect substitution between foreign and domestic varieties, perhaps due to quality differences. There are two possible wholesaler classifications $n$: wholesalers that sell both globally and domestically sourced products (multi-sourced wholesalers) and wholesales that only sell products from either international or domestic sources. This level of differentiation is entirely data driven; I cannot identify the origin of products shipped in a particular delivery from a multi-sourced wholesalers, nor do I observe repeat shipments from a given customer. When buyers make a choice for a particular purchase, I assume that the entirety of their purchase is from a single source, however they may make multiple purchases - which I do not observe. This buyer may have a systematic preference for using the same wholesaler for all purchases.

Formally $\epsilon$ is drawn from the distribution $F(\epsilon_{i,j}) = exp(-G(e^{-\epsilon_{i,j,o}}, ..., e^{-\epsilon_{i,j,W,O}}))$, where $G(\cdot)$ takes the functional form:

$$G(e^{\epsilon_{i,j}}) = e^{\epsilon_{i,j,o}} + \alpha_0 \left[ \sum_{o \in O} \left( \sum_{w,o \in S_o} e^{\epsilon_{i,j,w,o}/(1-\sigma_o)} \right)^{1-\sigma_o} \right] + \alpha_n \left[ \sum_{n \in N} \left( \sum_{w,o \in S_n} e^{\epsilon_{i,j,w,n}/(1-\sigma_n)} \right)^{1-\sigma_n} \right]$$

24 Purchase size $q_j$ is binned into nine groups for tractability.

25 In practice it is possible to have $2^3 - 1$ wholesaler classifications, iterating over the different foreign sources. However, estimation of that model provided quantitatively similar results to the simplified setup.
where weights \( \alpha_0 = \sigma_o / (\sigma_o + \sigma_n) \) and \( \alpha_n = 1 - \alpha_o \). Set \( \mathcal{S}_o \) includes all wholesaler-source combinations from source \( o \) and set \( \mathcal{S}_n \) includes all wholesaler-source combinations from wholesaler classification \( n \). The parameter \( \sigma = (\sigma_o, \sigma_n) \) must lie inside the unit circle. As either \( \sigma \) goes to zero, the corresponding weight goes to zero, rendering that dimension of product differentiation irrelevant. The first \( \sigma_o \) denotes the correlation of \( \epsilon \) between direct sourcing, indirectly sourcing from high-income foreign countries, and indirectly sourcing from low-income foreign countries. This allows for products sourced from abroad to be imperfect substitutes for domestically sourced products. The second \( \sigma_n \) denotes the correlation of \( \epsilon \) of multi-source and single-source wholesalers. This allows for domestic products sourced by globalized wholesalers to be imperfect substitutes for products sourced by domestic-only wholesalers.

**Conditional wholesaler market share** Within buyer type \( j \), the model aggregates across downstream buyers values over their buyer-specific shock \( \epsilon \). The probability of a purchase from wholesaler \( w \), conditional on a downstream purchaser type \( j \) is a function of mean valuation \( \delta_{j,w,o} \) and parameters \( \sigma \):\(^{26}\)

\[
s_{w,o|j} = s\left(\delta_{j,w,o}; \sigma\right). \tag{3}
\]

**Accounting for incorrect market size definitions** While markups only appear at \( t_2 \), they are heavily reliant on market size definitions. Small firms will charge a fixed markup that does not vary due to their size, large firms will exercise market power and charge a higher price. Mis-measured or inaccurate market definitions will skew analysis that attempts to gauge the role of market power. The use of aggregate data further complicates this; wholesaler data appears at the 5-digit NAICS level. For example NAICS code 42183 indicates all wholesalers that sell “Industrial Machinery and Equipment.” Such market definitions are overly broad and should be adjusted to account for hypothetical sub-markets.

As such, we introduce a new term \( \psi \) that considers the “addressable” market size. Firms compete with proportion \( \psi \) of the competition.\(^{27}\) The downside is that we cannot directly consider which firm is a direct competitor versus a firm that participates in a different “submarket”. This prevents us from considering the direct effect of a particular firm on another and consider more aggregate statistics in our counterfactuals.

This term will be disciplined directly by the use of establishment-level accounting data. See the discussion of identification in Section (4) for more details.\(^{28}\)

\(^{26}\)This function \( s(\cdot) \)'s closed form is derived in Appendix (B.5).

\(^{27}\)In a simple single logit demand specification, define the adjusted market share \( s_{w,o|j}^\psi \) of wholesaler \( w \) selling produce from source \( o \) to buyer of type \( j \) as:

\[
s_{w,o|j}^\psi = \frac{\exp (\delta_{w,o|j})}{\exp (\delta_{w,o|j}) + \psi_{w,o} \sum_{w'|o' \neq w,o} \exp (\delta_{w',o'|j})}.
\]

The coefficient \( \psi_{w,o} \) is implicitly defined as

\[
\exp (\delta_{w,o|j}) + \psi_{w,o} \sum_{w'|o' \neq w,o} \exp (\delta_{w',o'|j}) = \psi \sum_{w,o} \exp (\delta_{w,o|j}),
\]

where \( \psi \) is the proportion of competitors in a particular sub-market.

\(^{28}\)While this appears to be an ad-hoc solution, the alternative solution is to use a single market defined by the data, however as shown in Table (8), use of these localized market allow for markups to match the aggregate data.
**Wholesaler market share** The overall market shares of a wholesaler $w$ that is sourced from origin $o$ aggregates across a wholesaler’s market share across all $j$ types of buyers:

$$s_{w,o} = \sum_{j \in J} s_{w,o|j} \mu_j$$  \hspace{1cm} (4)

Where $s_{w,o|j}$ represents the market share of wholesaler $w$ with buyers of type $j$ and $\mu_j$ denotes the relative mass of buyers of type $j$. Observed and recovered wholesaler and product attributes are collected as $x = [p \ a \ \xi]$. While the mass of buyers $\mu_j$ is exogenous in this step, the next step endogenizes this choice.

### 3.3 Stage 3: Market Size

At $t_3$, downstream buyers make two decisions. First, buyers decide if they should make a purchase. Second, buyers decide how much to buy. Aggregated, these two steps establish the total downstream market size by considering both the mass of buyers and their purchase quantities.

Generally, discrete choice models assume that the total mass of possible buyers and their purchase quantities (conditional on buying) are fixed. This is rationalized as many standard discrete-choice models allow for buyers to not purchase a good. However, this assumption is not plausible across all intermediate manufactured good markets. If a set of wholesalers enter, perhaps supplying goods from a new foreign market, there may be an increase in the overall downstream market size. A wholesaler can expand the size of a market with a new product, changing their entry incentives.\[29\]

I combine both the number of buyers and how much they buy in a single step. In particular, I consider the elasticity of a market size for a buyer of type $j$ with respect to the valuation of all wholesaler options. While adopting a slightly different functional form, this stage follows Hausman et al. (1995), where buyers first choose quantity before choosing among a set of discrete choices. This quantity choice incorporates information from the choice set in a parsimonious manner and models a situation where buyers must pick their purchase quantities before receiving their idiosyncratic cost draws $\epsilon$.

In the absence of aggregate company size data for downstream buyers, I directly consider each downstream purchase as an independent purchaser.\[30\] The number of purchasers of type $j$ varies with the vector $x$ of wholesaler attributes. This allows for an increase in the number of purchases following increases in aggregate wholesale supplier quality. First, I denote the market share of purchases from buyer type $j$ as:

$$\mu_j = \frac{q_j M_j (x)}{\sum_{c \in J} q_c M_c (x)}.$$  

The set $J$ collects all possible types $j$. Let $M_j (x)$ denote the mass of downstream buyers of type $j$ and $q_j$ their purchase quantities. This function $M_j (x)$ captures two margins; downstream buyers can (a) choose to make a purchase or (b) change the quantity purchased due to changes\[29\]In Rysman (2004) the number of customers directly effects the willingness to pay for advertising. \[30\]An alternative formulation would consider the total purchase quantities, however this would require considering downstream buyers as ex-ante identical, before they make their purchase quantity decisions.

15
in market characteristics $\mathbf{x}$. I assume the number of downstream buyers $M_j$ is a function of their expected utility, parameterized as:

$$M_j (\mathbf{x}) = A_j \times (EU_j)^\phi.$$  
(5)

where $EU_j = E_j [\max_{w,o} U_{i,j,w,o}]$ denotes the expected utility for a buyer of type $j$ integrating across $\epsilon$. This expected utility is determined relative to the utility of directly sourcing from an upstream producer (outside option) and is determined up to a constant.

The parameter $\phi$ denotes the elasticity of the number of purchasers relative to the aggregate valuation of purchases. The shifter $A_j$ represents demand by downstream buyers of type $j$ in the absence of wholesalers. This form of two stage decision making is consistent with simple forms of cost minimization, when costs are fully realized after production choices.\(^{31}\)

Taking logs:

$$\log M_j = \phi \log [EU_j] + \log A_j.$$  
(6)

This relationship assumes that downstream buyers only realize shocks $\epsilon$ in equation (1) once they state their intent to buy a certain number of goods.\(^{32}\) This decision will rely only on the expectation of the shocks $\epsilon$, along with the set of purchase options and their attributes, which are summarized by $EU_j$ and $A_j$.

Parameters from both demand stages are collected as $\theta = [\alpha \; \sigma \; \phi \; \psi]$. With the downstream buyer choice problem fully described, the model now describes the behavior of wholesalers.

### 3.4 Stage 2: Wholesaler Pricing and Marginal Costs

In stage $t_2$, I assume wholesalers compete on price.\(^{33}\) This allows me to use a wholesaler’s profit maximization conditions to recover and decompose their marginal costs, and to measure operating profits.

Wholesalers first post their prices and then sell any quantity demanded at that price. As wholesalers are not directly involved in production, they can find sources to meet any reasonable demanded quantity in the short to medium run (for example, see Spulber (1999)).

Wholesaler $w$ maximizes their total operating profits:

$$\pi_w = \sum_{\omega \in O_w} (p_{w,\omega} - c_{w,\omega}) Q_{w,\omega} (p, \bar{x}; \theta),$$  
(7)

\(^{31}\)Formally shown in Appendix B. This discrete choice setup allows me to directly measure relative expected utility $EU_j$ using the overall wholesaler share, as $EU_j = (1 - S^W_j)^{-1}$. The variable $S^W_j$ is the summed market share of all wholesalers selling to buyer type $j$:

$$S^W_j = \sum_{w \in W} \sum_{\omega \in O_w} s_{w,\omega,j}.$$  

The set $W$ refers to all wholesalers, and the set $O_w$ refers to the sources for wholesaler $w$.

\(^{32}\)For example, suppose a downstream manufacturer is considering the use of a new chemical in their production process. If the manufacturer perceives these chemicals to be cheap, they will choose to make a purchase; otherwise, they will not.

\(^{33}\)I assume pure-strategy prices, that are assumed to be uniquely determined. This is a typical assumption in the differentiated product demand literature, as in Nevo (2001); Eizenberg (2014). This assumption can by rationalized with the conditions imposed in Caplin and Nalebuff (1991).
where \( p_{w,o} \) and \( c_{w,o} \) represent the price and marginal cost of wholesaler \( w \)'s products from source country \( o \in \mathcal{O}_w \). \( \mathcal{O}_w \) denotes the set of sources for wholesaler \( w \).\(^{34}\) The function \( Q_{w,o}(\cdot) \) denotes the expected number of purchases conditional of all other wholesalers’ prices \( p \) as well as their non-price attributes \( \bar{x} = [x/p] \) and takes the form:

\[
Q_{w,o}(p, \bar{x}; \theta) = \sum_{j \in \mathcal{J}} s_{w,o,j}(p, \bar{x}; \theta) M_j(p, \bar{x}; \theta).
\]

The conditional share function \( s_{w,o,j}(\cdot) \) is defined in equation (3) and the market size function \( M_j(\cdot) \) is defined in equation (5) for different purchasers buying quantity \( q_j \).

Taking the derivative of operating profits with respect to prices and assuming profit maximization, I can derive the marginal cost \( c_{w,o} \) as a function of market observables and demand:

\[
c_{w,o}^* = c(p_{w,o}, Q_{w,o}, \frac{dQ_{w,o'}}{dp_{w,o}}; \forall o, o' \in \mathcal{O}_w).
\]  \( \text{(8)} \)

This is a function of not only wholesaler price \( (p_{w,o}) \) and quantity sold \( (Q_{w,o}) \), but also the sales responsiveness of wholesaler \( w \)'s product sourced from \( o \) (say internationally sourced) with respect to the price \( (dQ_{w,o}/dp_{w,o}) \) and the sales responsiveness to the price for some other product sourced from \( o' \) (say domestically sourced) sold by the same wholesaler \( (dQ_{w,o'}/dp_{w,o}) \).\(^{35}\)

These wholesalers face constant marginal costs \( c_{w,o}^* \), which are a function of observable, recovered, and unobserved wholesaler-source attributes:\(^{36}\)

\[
c_{w,o}^* = c(\tilde{x}_{w,o}, \nu_{w,o}) = \tilde{x}_{w,o} \gamma + \nu_{w,o}.
\]  \( \text{(9)} \)

The vector \( \tilde{x} = [x/p, \xi] \) includes wholesaler observables, such as the extent of international sourcing and number of domestic distribution locations, as well as the recovered wholesaler-source specific quality shock \( \xi \) from the demand choice stage. The model also allows for a univariate unobserved marginal cost shifter \( \nu \).

### 3.5 Stage 1: Wholesaler Market Entry

In stage \( t_1 \), wholesalers make entry decisions and pay fixed cost to realize their attributes \( \tilde{x} \), quality shocks \( \xi \), and marginal cost shocks \( \nu \). When entering the market, wholesalers make two simultaneous choices: their importing profile and the configuration of their domestic distribution network.

Following Berry et al. (2015), \( N \) wholesalers are observed entering as with configuration \( a \), which is composed of the sourcing strategy \( s \subset \mathcal{S} \) and location configuration \( l \subset \mathcal{L} \). Sourcing strategies can take one of several main forms: wholesalers can choose to source domestically, from high-income foreign sources, and/or source low-income foreign sources. Furthermore, wholesalers can choose the number of foreign varieties to source. Combined, these possibilities form the set

\(^{34}\)For example, a multi-source wholesaler must choose a price for their domestically sourced and internationally sourced products.

\(^{35}\)See Appendix C for a full derivation.

\(^{36}\)Constant marginal cost does not imply constant returns to scale, as wholesalers pay upfront fixed costs to realize attributes \( x \) and receive quality draw \( \xi \) in the first stage.
\( S \). In terms of distribution, wholesalers can choose to set up distribution in any of the fifty states along with the District of Columbia.

As in most entry models, this model does not necessarily have a unique equilibrium. It is possible that one equilibrium allows for only small wholesalers and another equilibrium allows for only large wholesalers. However, fixed entry costs may still be identified in these models, under the assumption that the current market configuration is an equilibrium.\(^{37}\) In particular, two conditions must hold: (1) wholesalers will only enter if their expected operating profits are greater than entry costs, and (2) additional wholesalers (with a set of attributes \( a \)) will not earn expected operating profits greater than entry costs. Once wholesalers pay these fixed costs \( E_a \) and enter the market, each wholesaler receives a draw \( \xi \) that shifts a buyer’s valuation, and \( \nu \) that shifts marginal costs for the products sold.

Returning to the equilibrium conditions, (1) implies that the upper bound of entry cost \( \bar{E}_a \) is:

\[
E_a \leq \mathcal{E}^N_{\xi,\nu} [\pi (a) | N] = \bar{E}_a
\]  

(10)

The notation \( \mathcal{E}^N_{\xi,\nu} [\cdot | N] \) denotes the expectation over random variables \((\xi, \nu)\) conditional on \( N \) wholesalers with attributes \( a = (s, l) \) participating.

If the current market configuration is an equilibrium, then it would be unprofitable for an additional wholesaler to enter with sourcing strategy \( s \) and location configuration \( l \). Condition (2) then implies that the lower bound of the entry cost \( E_a \) is:

\[
E_a = \mathcal{E}^{N+1}_{\xi,\nu} [\pi (a) | N + 1] \leq E_a
\]  

(11)

These bounds do not require a market entry equilibrium to be computed. Rather, they only require that the current configuration of firms is in equilibrium, which does not need to be unique. Only the computation of counterfactuals require new equilibria calculation.\(^{38}\)

4 Estimation and Identification

There are four sets of parameters to be estimated: buyer demand parameters \((\alpha, \psi, \sigma)\), aggregate demand parameters \((\phi, A)\), marginal cost parameters \(\gamma\), and fixed entry costs \(E_a\). Estimation and identification details are described in reverse chronological order, starting with demand, then supply, and finally considering entry.

4.1 Stage 4: Choice of Downstream Buyer

The demand parameters \(\alpha\), \(\psi\), and \(\sigma\) are identified by the distribution of prices, accounting markups, observed wholesaler attributes, plausibly exogenous instruments, aggregate statistics across downstream buyer types, and the timing assumptions from the multi-stage model. The price coefficient \(\alpha^p\) is identified directly from a set of geographic-based cost-shifters. The geographic and quantity based buyer valuations \(\alpha^l\) and \(\alpha^q\) are identified using a series of closely

\(^{37}\)For an example, see Berry et al. (2015).

\(^{38}\)Extensions consider the fixed costs of changing the configuration of a particular wholesaler. Wholesalers must not find it profitable to deviate from their current configuration and this allows us to infer the particular costs of changing from \(a\) to \(a'\). Such approaches are considered by Eizenberg (2014); Pakes et al. (2015).
related aggregate moments. The parameters $\alpha^a$ and $\sigma$ are identified from the set of observed wholesaler attributes combined with the two-stage entry game assumptions from Section 3. Market competition parameter $\psi$ is estimated directly from changes in accounting markups and prices. Parameter $\sigma$ is also identified using geographic variation in the wholesaler choice set for downstream buyers. The central assumption, common in demand estimation, is that buyer preferences are both time-invariant and location-invariant (up to a series of fixed effects). Identification of preferences derives from variation in choice sets due to factors exogenous to demand. To simplify computation, I discretize the types of downstream buyers. I use 51 geographic bins (the fifty US states + DC) and nine purchase size bins (as shown in the data section).

**Price Instruments** An identification issue arises from the potential correlation between unobserved quality $\xi$ and wholesaler price $p$. Prices in differentiated product supply system are directly related to the unobserved quality $\xi$, as wholesalers will charge higher prices for higher quality products. Thus, a standard ordinary least squares regression of price on market shares may bias price coefficients upwards. The simplest instruments are signals of marginal costs, which are correlated with a wholesaler’s cost but not the buyer’s valuation $\xi$. These instruments shift cost and are related to prices in the vast majority of supply models. In my data, I have wholesaler-level accounting cost data $\tilde{c}$, which do not directly measure marginal costs, but are an informative signal. However, I explicitly assume that marginal costs $c_w$ are functions of quality $\xi_w$; thus, instrumenting a wholesaler’s own cost on the wholesaler’s price is inherently problematic.

Instead, I combine the geographic nature of the Hausman et al. (1994) and Nevo (2001) instruments with standard cost-based instruments. Assume that marginal costs $c_w$ for wholesaler $w$ has two components, $c_{w,\xi}$ and $c_{w,l}$, where $c_{w,\xi}$ is correlated with $\xi$. Component $c_{w,l}$ is due to the unobserved cost of doing business in a particular location $l$. This includes warehouse rents and fork-lift operator labor costs. While these costs are unobserved, I use the observed average operating costs of other wholesalers in different product categories within nearby geographic regions. These costs $c_{-w}$ only share their component $c_{-w,l}$ with $c_w$ and are thus correlated. As cost $c_{-w,l}$ is uncorrelated with $\xi_w$, the independence assumption is satisfied.

As marginal costs are not directly observable, I use accounting cost data and form instruments by aggregating across wholesalers in unrelated wholesale sectors at the ZIP code, county, and state levels. I denote this accounting cost $\tilde{c}_{-w,l}$. For example, accounting costs of medical equipment wholesalers in New Haven county will be used as a price instrument for industrial chemical wholesalers. This strategy assumes that the unobserved product quality for an industrial chemical wholesaler will be uncorrelated with accounting costs for medical equipment wholesalers. I collect these shifters as instruments $Z_1$.

**Aggregate Shipment Moments** Aggregate data on shipment patterns identifies the preference (a) between sourcing indirectly from a wholesaler and directly from a manufacturer conditional on purchase sizes and (b) between sourcing from a local and a distant source.

39Implicit is the assumption that downstream demand is not correlated across industries. However, each of these product groups are small relative to the overall local economies.
Large purchases tend to be sourced directly from manufactures and small purchases tend to be sourced indirectly through wholesalers. This purchase-size dependent desirability of direct sourcing versus indirect sourcing is identified by using the estimated aggregate wholesaler market share for a given quantity $q$:

$$s_{W|q} = \sum_{w \in W} \sum_{n \in O_w} \sum_{j \in J_{q}} s_{w,o\|j} \mu_j,$$

where $s_{W|q}$ denotes the total market share of all wholesalers conditional on buyer size $q$. This is a function of conditional market share $s_{w,o\|j}$ and buyer weights $\mu_j$. Additionally, $W$ represents the set of all wholesalers, $O_w$ represents the set of wholesaler $w$’s sources, and $J_{q}$ represents the set of buyer types $j$ that purchase $q$ units.\(^{40}\)

In a similar vein, the desirability of a local wholesaler versus a distant wholesaler is identified by matching the estimated share of local, regional, and national shipments to their observed shares:

$$s_{W|d} = \sum_{w \in W} \sum_{n \in O_w} \sum_{j \in J} s_{w,o\|j} \mu_j \mathbb{1}\{l_j = l_w\}$$

The indicator function identifies shipments that do not cross state or regional lines, where the location of the buyer and the location of the wholesaler correspond. The set $J$ sums across all buyer types $j$. This identifies $\alpha^q_j$ as $s_{W|d}$ differs from the unconditional share due to differences in $s_{w,o\|j}^q$ across wholesalers $w$.

In addition, the share of consumers sourcing from wholesaler that (1) source products domestically, (2) that source products globally, and (3) that source both products, in each geography is matched to observed data. This also helps partially identify the nested logit parameter $\sigma$, along with $\alpha^l_j$. Collectively, I denote these moments as $m_1$.

**Aggregate Markup Moments** Industry trends in markups identify $\psi$. For each period and industry combination $W$, I compute aggregate accounting markups as:

$$\mu_{W,t}^{accounting} = \frac{\sum_{w \in W} Revenue_t}{\sum_{w \in W} Operating\ Cost_t}$$

Assuming that these markups are consistently biased across time, with $Operating\ Cost_{W,t} = \epsilon^{OC} \times Variable\ Cost_{W,t}$ and under the constant marginal cost assumption from the supply-side of Section (3), the relative accounting markups are directly related to actual markups $\mu_{W,t}$:

$$\frac{\mu_{W,t}^{accounting}}{\mu_{W,t-1}^{accounting}} = \frac{\mu_{W,t}}{\mu_{W,t-1}}$$

In addition, this can be done for any other subgroup of firms $W'$, I consider combinations of wholesalers by global and domestic sourcing; as well as multi-location and single-location wholesalers. I collect the logarithms of these relative accounting markups by industry from 1997 to 2007. As the level of markups without variable market power is pinned down by $\alpha^p$, this

\(^{40}\)This relationship helps identify $\alpha^q_j$, as $s_{W|q}$ differs from $s_{W|q'}$ due to $\log(q)$ in equation (2).
moment pins down effective market size $\psi$ from the changes in markups over time. I denote these moments $m_2$.

**Correlation Coefficients** Estimation uses two additional sets of instruments to identify the nested logit correlation parameter $\sigma$. The first assumes that buyers have similar preferences, but some have different choice sets, due to regional variations in wholesaler networks. The second uses the fact that even without wholesalers, there would be a downstream market, and uses estimates of this counterfactual downstream market size as an instrument.

**Nest Market Share Shifters** The first instrument’s identification strategy follows the logic of Berry et al. (1995). Essentially, different downstream buyers face different choice sets due to wholesaler geographic differentiation. A wholesaler’s entry choices are made before quality $\xi_{w,o}$ is drawn, allowing the number and attributes of competitors to identify $\sigma$. In practice, if there are many (few) wholesalers, then within observed wholesaler market shares will be small (large). The intuition behind this is illustrated in a simplified case without observable downstream buyer heterogeneity and one nest. The demand share equation then takes the form:

$$\ln (s_{w,o}) - \ln (s_0) = \alpha p \log p_{w,o} + \sigma \ln (s_{w,o|o}) + \xi_{w,o}.$$  

The sales share of a wholesaler $w$ selling a product sourced from $o$, conditional on selling products from $o$ is denoted $s_{w,o|o}$. This variable is naturally correlated with $\xi_{w,o}$ as wholesalers with higher quality draws will not only have higher unconditional market shares, but higher market shares conditional on their attributes. Thus, a valid instrument needs to satisfy the exogeneity criterion, but at the same time relate to the regressor of interest. As the number and attributes of wholesalers is chosen before the realization of $\xi$, exogeneity is satisfied. The estimation strategy generalizes this to include the number of wholesalers with the same sourcing strategy (single-source or multiple-source) and sourcing from particular locations (domestically, high income foreign sources, and low income foreign sources) at the regional and state level.\(^{41}\) I collect these instruments as $Z_2$.

**Aggregate Market Size Shifters** The second instrument uses size of the downstream market as a shifter for the number of wholesalers present. This assumption is similar to that in Berry et al. (2015), where the total population of a consumer market is plausibly exogenous. The larger the market, the greater the possible profits and thus more wholesaler entry. However, unlike Berry et al. (2015), this strategy requires a modification to split the total downstream market size into two components: one part endogenous to the presence of wholesalers and the other part exogenous to the presence of wholesalers.

While the total market downstream market size is endogenous, there also exists an exogenous “choke” market size, the size of the market without the presence of any wholesalers. This is consistent with location choices of upstream manufacturing suppliers occurring in a pre-period. The number of downstream buyers in this world is related to a baseline demand; in markets with a high downstream baseline demand, many wholesalers are likely to enter, driving down

\(^{41}\)Estimation considers the logarithm of these variables.
realized market shares. Formally consider the value $A_j$ from Equation 5. Even if the total value of wholesaling is zero, downstream market demand is realized as $M^{CF}_j = A_j$. By summing across discrete buyer types $j$, total counterfactual downstream demand without wholesalers is:

$$M^{CF} = \sum_{j \in J} M^{CF}_j.$$  

The estimation routine uses the logarithm of a local demand version for location $l$.\textsuperscript{42} I collect these instruments as $Z_3$ after averaging across all the states with the presence of a particular wholesaler $w$.

**Empirical Implementation**

Estimation follows Petrin (2002), adapted to a multiple-stage nested-logit model with observably heterogenous agents. Conditional on parameters and observable data, equations (2) - (4) produce estimates for unobserved quality $\xi$ and aggregate moments $m$. A generalized method of moments objective function is constructed using the following two sets of moments:

$$Z'\xi = 0$$
$$m_{data} - m = 0$$

The matrix $Z$ consists of cost-shifters ($Z_1, Z_2, Z_3$) and the other exogenous observable attributes of a wholesaler (the data $X$, excluding prices $p$), which are assumed to be chosen before the shock $\xi$ is known. The vector $m_{data}$ consists of the empirical analogs of estimated aggregate moments ($m_1, m_2$). See Appendix B.5 for a full description of the empirical estimation routine.\textsuperscript{43}

### 4.2 Stage 3: Market Size

The first stage of demand is identified simultaneously with the second stage. I seek to (a) estimate the elasticity $\phi$ of the number of downstream purchasers with respect to the aggregate mean utility from wholesalers and (b) recover the the size of the market without wholesalers, $A$.

Estimation uses equation (6), reproduced below:

$$\log M_j = -\phi \log [1 - S^W_j] + \log [A_j].$$

This equation shows that the relative value of wholesalers compared to direct sourcing is entirely captured by aggregate wholesaler market shares.\textsuperscript{44} The object of the estimation is to provide $A_j$ for use as an instrument in the discrete choice estimation and parameter $\phi$ to identify the elasticity of aggregate demand. To better explain the identification strategy, I first

\textsuperscript{42}The sum aggregates across the set $J_l$, the set of buyer types $j$ in location $l$.

\textsuperscript{43}Geographic controls are included at the census-division-market level as a robustness check. Results are largely unchanged.

\textsuperscript{44}The expected utility in such discrete choice models is simply the inverse market share of the choices: $EU_j = 1/(1 - S^W_j)$.
elaborate on the level of observation. Each \(j\) is composed of three elements: downstream product category \(c\) (which is defined at the year-product level), downstream location \(l\), and downstream purchase quantity \(q\). Denoting \(M_{c,q,l}\) as the total observed downstream purchases and \(S^{W}_{c,q,l}\) as the aggregate wholesaler purchase share for product \(c\), in region \(l\), where the shipment size is \(q\) units, I estimate the following relationship:

\[
\log M_{c,q,l} = -\phi \log [1 - S^{W}_{c,q,l}] + \lambda_{c,l} + \lambda_{c,q} + \lambda_{l,q} + \lambda_{c,q,l}.
\] (12)

The covariate \(\lambda_{c,l}\) represents a fixed effect for a particular product \(c\) sold in region \(l\), \(\lambda_{c,q}\) represents a fixed effect for a particular product \(c\) sold at quantity \(q\), and \(\lambda_{l,q}\) represents a fixed effect for shipments of quantity \(q\) in a given region \(l\). These covariates represent the local demand for certain products, the general nature of that demand, and the market size of that downstream location. The last term \(\lambda_{c,q,l}\) represents the deviation of a particular \((c, q, l)\) from the three previous fixed effects. The residual term \(A_{j}\) equals \(\exp (\lambda_{c,l} + \lambda_{c,q} + \lambda_{l,q} + \lambda_{c,q,l})\), where the first three linear terms are controlled for, but the last term is unobserved. Then collect the set of residual demand shifters in vector \(A = \{A_{j}\}\).

Estimation assumes that \(E[X_D \lambda_{c,q,l}] = 0\), where \(X_D\) includes share of goods sourced from wholesalers and the three fixed effects. Econometrically, the last lambda, \(\lambda_{c,q,l}\) is not controlled for and may be correlated with wholesaler market shares. A related econometric risk is reverse causation: higher demand \(M\) may induce more wholesaler entry. Due to the timing assumptions made, structure of demand and explicit product-location fixed effects controlling for wholesaler and overall downstream demand presence, I explicitly rule this out. An alternative view of this assumption is that aggregate demand shocks affect both large and small purchases similarly; the difference between large and small purchases is entirely accounted for by wholesalers.\(^{45}\)

### 4.3 Stage 2: Wholesaler Pricing and Marginal Costs

Wholesaler marginal cost identification proceeds in two steps. First, demand estimates help back out implied marginal costs, \(\hat{c}_{w,o}\) for each wholesaler \(w\) and source \(n\) combination. Second, marginal cost parameters \(\gamma\) are estimated using ordinary least squares.

Marginal costs are directly derived from equation (8). They are a function of the demand parameters \(\theta = (\alpha, \sigma, \phi)\), the recovered product qualities \(\xi\), and aggregate demand shifters \(A\), all conditional on observed and recovered data \(X = [p \ a \ \xi]\).\(^{46}\)

\(^{45}\)Identifying variation in can be summarized as follows. Consider the sales of industrial chemicals in Connecticut. Estimation looks at the deviation in the number of large and small orders from both the Connecticut averages for those orders, as well as at the deviation within industrial chemicals. Additionally, in contrast to the sixty product markets (over three years) used in the discrete choice estimation, a more refined set of over 400 products are used in this estimation.

An alternative instrumentation strategy would be to use geographic variables exploiting changes in wholesaler costs across regions, as done in the last demand stage. For robustness, data is aggregated up to the product-location level and the suggested instrumentation strategy is used, dropping product-location fixed effects. While the magnitude of \(\phi\) is slightly larger, results are broadly similar.

\(^{46}\)In implementation, this step needs function \(M_{f_j}\), requiring the demand parameter \(A_{j}\). In the estimation of demand, \(A_{j}\) is assumed to have an idiosyncratic component \(\lambda_{c,q,l}\). (See equation (12)). The estimation routine therefore uses the distribution of \(\lambda_{c,q,l}\) to produce an estimate of the expected value of \(A_{j}\): \(\hat{A}_{j} = \mathbb{E}(A_{j})\). The econometric specification in 12 assumes that \(E[\lambda_{c,q,l}] = A\). This step uses the resulting distribution of \(\lambda\) and takes an exponential transformation to derive the expectation of \(A\).
Once recovered, wholesaler attributes can be projected onto these marginal costs. Marginal costs \( \hat{c}_{w,o}(\theta, A; X) \) are a function of wholesaler attributes:

\[
\log \hat{c}_{w,o}(\theta, \xi, A; X) = \tilde{x}_{w,o} \gamma + \nu_{w,o},
\]

where \( \tilde{x} = [x/p] \) are all characteristics after omitting price. As a slight departure from the standard methodology, marginal costs are a function of unobserved quality \( \xi \). Products with higher \( \xi \), especially concerning better customer service or availability, are likely to incur higher marginal costs. The structural error \( \nu_{w,o} \) is assumed to be known only after all wholesaler attributes are chosen, but before markups are chosen. I assume that there exists \( Z_\nu \), such that \( E[\nu Z_\nu] = 0 \). As quality \( \xi \) and wholesaler attributes \( x \) are chosen or realized in an earlier period, these characteristics form a plausible vector \( Z_\nu \).

In the empirical implementation, standard errors are computed using a parametric bootstrap, where demand estimates are assumed to be a multivariate normal distribution with an estimated variance-covariance matrix. Bootstrap draws from this distribution produce estimates of \( \theta_{BS} \) that are used to recompute \( \xi_{BS}(\theta_{BS}) \) and \( \hat{c}_{BS,w,o}(\theta_{BS}, A; X_{BS}) \). These new estimates for \( \xi_{BS} \) and \( \hat{c}_{BS} \) are then used to produce standard errors for estimates for marginal cost parameters \( \gamma \).

### 4.3.1 Dealing with wholesalers participating in both domestic and international trade

The underlying data only provides prices for wholesalers that source from a single source. Prices for multi-product wholesalers are only reported in aggregate. To get prices and costs by source, multi-product wholesaler details are recovered separately using data from single-product wholesalers. The primary estimation of stages \( t_1 \) and \( t_3 \) are done only for single product wholesalers. This stage recovers the parameters for multi-product wholesalers that source both domestically and from abroad. This is a product-side interpretation of the logic underpinning De Loecker et al. (2016).

For exposition, assume a wholesaler sells both a domestically sourced product \( D \) and an internationally sourced product \( F \). Instead of observing prices \( p_{w,F} \) and \( p_{w,D} \) separately for goods sourced internationally and domestically, I only observe the sales weighted average \( \bar{p}_w \), where the weights are the known sales shares, \( M_{w,F} \) and \( M_{w,D} \). The pricing estimation stage recovers multiplicative markups \( \mu_{w,F} \) and \( \mu_{w,D} \), as well as data on single-product wholesalers on \( c_w(\cdot) \).

Generalizing away from downstream buyer heterogeneity, this produces the following relations governing prices and costs:\(^{47}\)

\[
\bar{p}_w = M_{w,D}p_{w,D} + M_{w,F}p_{w,F}
\]

\[
p_{w,D} = \mu_{w,D}c_{w,D}
\]

\[
p_{w,F} = \mu_{w,F}c_{w,F}.
\]

To close the system, assume that the unobserved component of cost \( \nu_{w,t} \) is identical across

\(^{47}\)For details on markup calculations see Appendix C.
domestically and internationally sourced goods, rewriting equation (13) as:

$$\log c_{w,F} - \log c_{w,D} = x_{w,F} \gamma F - x_{w,D} \gamma D$$ (17)

This is justified as wholesalers appear to provide the same levels of customer service to their downstream buyers, even if product acquisitions costs observably differ, once attributes $x$ (including recovered product quality) are accounted for. A product that originates from China likely is handled and shipped by the same local warehouse worker as a product produced in Alabama.

Equations (14) - (17) can be combined to solve for $p_{w,D}$, $p_{w,F}$, $c_{w,D}$ and $c_{w,F}$. This technique is easily generalizable to more than two products.

4.4 Stage 1: Wholesaler Market Entry

Market entry cost estimation utilizes a set of equilibrium assumptions. As direct evidence on fixed costs is sparse, they are recovered indirectly. Bounds for wholesaler entry costs ($E_a$) for a wholesaler with configuration $a$ directly uses two equilibrium conditions: (1) wholesalers will only enter if their expected operating profits are greater than entry costs, and (2) additional wholesalers of the same configuration will not earn expected operating profits greater than entry costs. As shown in equations (10) and (11), these equilibrium conditions imply upper bounds $\bar{E}_a$ and lower bounds $\underline{E}_a$ on entry costs. The following empirical analogs are computed:

$$\mathbb{E}_{\xi,\nu} [\pi (a) | N] = \bar{E}_a$$

$$\underline{E}_a = \mathbb{E}_{\xi,\nu} [\pi (a) | N + 1],$$

where $\mathbb{E}_{\xi,\nu}$ is the expectation over the distribution of quality deviation $\xi$ and marginal cost shocks $\nu$, which take the joint distribution $G^{a}_{\xi,\nu}$ for wholesalers of configuration $c$. The upper-bound takes the expectation of net profits for the number of wholesalers $N$ as observed currently in the market. The lower-bound takes the expectation of net profits when an extra wholesaler, or $N + 1$ wholesalers are present in the market.

These bounds are empirically implemented by simulating counterfactual net profits $\pi_a$ for each wholesaler configuration $a$. This estimation technique can hypothetically provide extremely wide bounds. In practice, due to the number of wholesalers typically available in a market, bounds are relatively narrow, with the exception of the very largest wholesalers.48

5 Results

5.1 Stage 4: Choice of Downstream Buyer

Table 5 reports results from the estimation of downstream buyer choices. All coefficients, except for $\sigma$, are relative to direct purchases from manufacturers. As noted in Section 4.3.1, estimates

48Such bounds are computed for every every possible observed configuration of a wholesaler. As there technically are $2^{51}$ possibilities for wholesaler location choices, not all possible configurations are seen in the data and the counterfactual will only consider the number of locations, not the specific configuration. This revealed preference approach can extended to consider the costs for a particular wholesaler to change their configurations. This is left for future research.

**Fixed Effects**: 3-Digit Industry $\times$ Source, Year $\times$ Source

**Notes**: Results from an optimizing generalized method of moments (GMM) routine using a derivative-free gradient search. Robust GMM standard errors presented. See text for full regression specification. North refers to high-income country sources. South refers to low-income country sources.

are derived from single-source wholesalers.

Buyers are extremely price sensitive, and the estimated price coefficient implies that wholesalers face elastic demand. Wholesalers with multiple locations are generally more appealing than those with few locations, regardless of whether they are present in the same location as a downstream buyer. Omitted fixed effects control for market-source and year-source deviations in valuations.

Three coefficients consider the importance of observed downstream buyer heterogeneity and are precisely identified by the aggregate moments. A wholesaler in the same state, and to a lesser extent in the same census region, is extremely valuable for downstream buyers. Similarly, the benefit to indirect sourcing versus direct sourcing is declining in shipment size. Quantifying the buyer tradeoff between scale and indirect sourcing, wholesalers provide almost no benefit to downstream buyers receiving the largest shipments. Estimates for $\psi$ show that typical data-implied market size is about 1/6 ($1/.179 \approx 6$) the market size implied by naive use of administrative data.

The nest coefficients $\sigma$ relate to the substitutability between internationally sourced and domestically sourced goods, as well as between wholesaler with different product availabilities (single-source versus multi-source). A value of 1 implies zero substitutability between these categories, and a value of 0 implies no differentiation in the substitutability between categories. I find there to be imperfect substitutability between domestically and internationally produced varieties ($\sigma_o$), as well as between wholesalers with different sourcing strategies ($\sigma_n$). This is

---

49 Estimation in a simplified model without downstream buyer heterogeneity shows the importance of price instruments. I obtain a significant positive coefficient on price, which would indicate that consumers like higher priced goods, even conditional on quality.

important since it implies that (a) internationally sourced varieties are imperfect substitutes for domestically sourced varieties and (b) multi-source wholesalers are imperfect substitutes for single-source wholesalers. An analogy from retail for (a) would be that Parmesan Cheese (from Italy) and Vermont Cheddar (sourced domestically) are imperfect substitutes. For (b), this implies that buying Parmesan Cheese from an Italian-only grocery store is different than buying the same cheese from Whole Foods.

### 5.2 Stage 3: Market Size

Estimates for the elasticity of the downstream market size with respect to expected utility from wholesaling are reported in Table 6. Columns (1) - (4) report results across various specifications. Shipments are binned in the same nine size categories as in the demand choice estimates. Locations consider the fifty disjoint US states as well as the District of Columbia. Product-year categories consider Standard Classification of Transported Goods (SCTG) good classifications, which are more disaggregated than the wholesaler NAICS categories used in the demand choice estimation. Columns (1) and (2) consider 4-digit SCTG categories and specifications (3) and (4) consider 5-digit SCTG classifications. In general, more disaggregated classifications lead to more fixed effects and higher \( R^2 \) values, even though the parameter estimates do not significantly change. Columns (2) and (4) weight results based on market size.

In general, all four specifications find precise parameter estimates for the elasticity \( \phi \) between 0.25 and 0.30. I will use estimates from specification (4) in the counterfactual analysis as well as subsequent estimation as it is robust to the greatest number of fixed effects and includes the finest level of disaggregation.

### 5.3 Stage 2: Wholesaler Pricing and Marginal Costs

Wholesaler-level marginal costs are broken down in Table 7 following equation (13) and regress the logarithm of marginal cost on a set of covariates. The specification includes product-markets-year fixed effects (at the 5-digit NAICS wholesale level). The marginal cost of distributing globally sourced products is 16-18% higher than distribution for domestically sourced prod-

...products. Similarly, higher quality shocks $\xi$ imply higher marginal costs, though this relationship is stronger for domestically sourced products than internationally sourced ones and this relationship is weakening over time. Finally, wholesalers with many domestic distribution locations have slightly lower marginal costs, perhaps reflecting better optimization technology.

Implied Markups To gauge the importance of considering localized, geographically linked markets, Table 8 compares implied markups and marginal costs across three scenarios. Panel A considers the mean wholesaler’s marginal cost of delivering $1 of upstream producer output to a downstream buyer. Panel B displays the mean wholesaler markup for delivering the same $1 of upstream producer output to a downstream buyer. Panel C presents the implied aggregate profits from equation 7. In each panel there are three rows. The first presents results from the full localized demand model, the second from a model with a single national market (without submarket, thus $\psi = 1$), and the last from a model with monopolistic competition. These comparisons are relevant as the vast majority of international trade models consider monopolistic competition.

In terms of marginal costs, the full model produces marginal costs about 6-9% lower than monopolistic competition, markups 6-10% higher than monopolistic competition, and implied operating profits 30-60% larger. This difference is even starker when looking at the change across time to marginal costs and markups. From 1997 to 2007, marginal costs decrease under the full model and actually increase in the simple monopolistic competition model. Similarly, the mean markups increase under the full model and stay fixed in the baseline monopolistic competition model. Even if the differences between models are considered small within a cross-section, the inter-temporal trends are relevant. Essentially, a wholesaler may have a small localized monopoly (say within New England) and may exert market power with only small buyers in that region alone. The full “localized markets” model accounts for this market power, while...

**Notes:** Marginal costs and markups derived from equation (8). Wholesaler operating profits derived from equation (7). Localized markets imply downstream customer heterogeneity and wholesaler market power. National markets allow for wholesaler market power at the national level ($\psi = 1$), but no downstream customer heterogeneity. Monopolistic competition shuts down both downstream customer heterogeneity and wholesaler market power. Results are the sums across all considered wholesale markets.

models with a single national market average out wholesaler market shares across markets and thus attenuate any market power findings. The standard monopolistic competition model finds constant markups over time, contradicting Fact 3, which finds that markups are increasing over time.

### 5.4 Stage 1: Wholesaler Market Entry

Table 9 considers the lower and upper bounds of fixed entry costs $E_a$ for various wholesaler configurations $a$. While the underlying calculations are done by wholesaler category and industry, displayed results are the product of wholesaler and market characteristics regressed on fixed entry cost estimates. These results are further binned by broad groupings $a'$. Additionally, due to small sample sizes, wholesalers that only participate in international trade are combined with wholesalers that participate in both domestic and international trade.

For a wholesaler that operated one domestic distribution location in 1997 and only sourced domestically, fixed entry costs are around $500,000. Similarly, wholesalers that participate in international trade and operate in at least four states have fixed costs between $150 and $250 million dollars, which are reasonable considering billions in yearly sales. This discrepancy is even greater for wholesalers in 2007. Moreover, this table shows that the biggest gains in operating profits accrue to wholesalers that both participate in international trade and have extensive domestic distribution networks.

**Notes:** Each cell displays bounds for fixed entry costs. Results are the product of regression of wholesaler and market characteristics regressed on fixed entry cost estimates.

6 **Model Implications**

The probability of a buyer sourcing from a wholesaler has increased about 35% from 1997 to 2007, even though the number of wholesalers has fallen. There are multiple channels to decompose out buyer gains from wholesaling. These include changes in buyer types, wholesaler varieties, prices, economies of scale and quality (which can be further decomposed into gains from domestic and international sourcing strategies), and local product availability. What are the relative importance of each of these channels? Table 10 decomposes these gains through the lens of the demand and pricing models.

I compute the following statistic for a variety of counterfactuals:

$$\hat{s}_W = \frac{s_W(x^{2007}) - s_W(x^{CF})}{s_W(x^{2007}) - s_W(x^{1997})}.$$  

Where $s_W(\cdot)$ is the aggregate market share of wholesalers, $x^{2007}$ refers to data from 2007, $x^{1997}$ refers to data from 1997, and $x^{CF}$ refers to a particular counterfactual. In these counterfactuals, I first fix all attributes of a wholesalers to their 2007 levels and then adjust the object of interest to match the mean in 1997.

Table 10 nets out difference in the distribution of downstream buyers\(^5\) and considers changes in four categories; price effects, domestic distribution networks, domestic and international sourcing, and the variety of wholesalers. Column (1) displays these results considering the average of these effects across all sample markets. These changes are further broken down according to the size of the wholesalers. The components do not sum to 100% due to interactions between factors. Columns (2), (3), and (4) consider the smallest 90% of wholesalers, the middle 90-99% of wholesalers, and the largest 1% of wholesalers respectively. Positive numbers indicate changes that are surplus enhancing for buyers and negative numbers indicate changes that are surplus

\(^5\)Formally, counterfactuals are run considering only the composition of buyers in 2007; the changes in wholesaler market shares due to changes the composition of buyers in 1997 are netted out. In addition the underlying individual counterfactual decompositions do not linearly sum up to 100% as effects can interact both positively and negatively.

</table>

**Notes:** This table decomposes changes to the market shares of wholesaler distribution versus direct distribution from 1997 to 2007. The table decomposes this by various changes to wholesaling from 1997 to 2007. For example, the first column of the first line states that wholesaler market share in 1997 would be 20% smaller than the observed wholesale market share if wholesalers charged prices similar to 2007. Data is averaged across markets and normalized to account for changes in market sizes.

The first channel considers changes in prices, which are decomposed into changes in markups and marginal costs. As average wholesaler prices increase, this effect works against an increase in wholesaler market share. If 1997 wholesaler prices were offered in 2007, the increase in wholesaler market share would be 10 percent larger. This change is driven by both decreases in marginal costs and increases in markups. As shown in Section 5 and Table 7, both internationally sourced products and high quality domestic distribution incur higher marginal costs. While smaller in comparison, markups also increase, reflecting increased market power, primarily for the largest 1% of wholesalers.

The second channel reflects changes in domestic distribution networks due to more comprehensive regional and national warehouse location choices. This accounts for 40% of the total gain in aggregate wholesaler market shares. In particular, the largest wholesalers have drastically scaled up in size and offer local distribution to a greater subset of domestic buyers.

The third channel considers the changes to the quality of domestic sourcing and international sourcing through wholesalers. Changes in domestic sourcing account for 3/4 of this change, and changes to international sourcing account for the remaining 1/4. This reflects either better customer service for downstream buyers or more comprehensive procurement strategies from wholesalers. Wholesalers may offer more varieties within each category. While the changes to the quality of domestically procured products are distributed among wholesalers in proportion to wholesaler market size, changes to the quality of internationally procured products accrue mostly to the largest wholesalers.

The last channel is due to the presence of idiosyncratic downstream buyer-wholesaler preference shocks. Downstream buyers choose the source with the highest value (or lowest cost) inclusive of these shocks. As the number of wholesalers decrease, wholesale market share me-
chanically falls, as downstream buyers receive fewer shocks to choose from. If the number of wholesalers in 2007 was at 1997 levels, the change in wholesaler market share would be 1% smaller.

7 Gains from Intermediated International Trade

To quantify the downstream effects of intermediated international trade and innovations in wholesaling, I focus on the role of international trade and shut down indirect importing by downstream buyers. While downstream buyers can still import foreign products by directly sourcing from abroad (in the outside option), they can no longer indirectly source foreign goods through wholesalers.\footnote{In the Appendix, I consider a second scenario that measures aggregate gains in the wholesaling industry from 1997 to 2007, i.e. the inter-temporal gains.}

I conduct two forms of counterfactuals; one fixes the set of wholesalers and the other allows for wholesaler entry/exit. The first counterfactual design considers the current set of wholesalers to be fixed and restricts them to only distributing domestically sourced products. Even without new entry and market repositioning by existing wholesalers, this simulates the short-run changes in outcomes due to wholesaling. The second counterfactual design takes seriously the role of wholesaler entry and exit. By restricting wholesaler participation in international trade, a subset of wholesalers may exit and another subset of wholesalers may enter. This counterfactual computes alternative equilibria, using a simplified wholesaler choice set, and their market implications. If particularly valuable wholesalers (from a buyer perspective) exit, this could lead to negative consequences. However, if entering wholesalers exert less market power than exiting wholesalers, this could lead to positive outcomes.

7.1 Counterfactual 1: Fixed Set of Wholesalers

Table 11 summarizes the market effects of indirect international sourcing under the two counterfactuals. The first set of columns presents baseline results for 1997, 2002, and 2007. The second set of columns, labeled “Counterfactual 1,” summarizes changes due to indirect international sourcing, considering wholesaler price responses, but not wholesaler entry/exit decisions. The third set of columns labeled “Counterfactual 2” allows for wholesaler entry/exit and is discussed in the next section. Panel A displays the results of each counterfactuals in levels. Panel B considers changes in wholesaler profits and changes in downstream buyer surplus.

In this scenario, as shown in Panel A, market size and wholesaler market shares slightly decrease in all three years. This reflects the value downstream buyers place on sourcing products from abroad through wholesalers. Wholesaler market share falls, as international sourcing is heavily concentrated in the largest wholesalers. This also causes a similar decrease in markups.

Panel B considers the changes in market outcomes. In 1997, the loss of indirect international sourcing by wholesalers would reflect a $150 billion loss in surplus (in 2007 dollars), or 4.0% of downstream expenditures. Analogously in 2007, the loss would reflect a $230 billion decrease in surplus, or 4.4% of downstream expenditures.\footnote{This figure assumes that the outside option - sourcing from manufacturers is unchanged. This discrete choice framework is unable to distinguish what are the gains due to changes in the outside option, rather just changes in their attractiveness.}

Notes: Static gains are computed as the compensating variation needed to maintain the same expected utility for downstream customers, assuming no changes in the number, type or prices of wholesalers. Static gains allow wholesalers to change their prices in response to changes in their ability to source international varieties. Entry/Exit gains allow wholesale firms to enter or exit the market due to changes in fixed costs and operating profits due to change in international sourcing. All figures in Billions of 2007 dollars.

Notes: Profits re-computed after resolving iteratively for best-response prices, holding fixed the number of wholesalers.

downstream market size due to indirect international sourcing. In 1997, total manufactured good purchases would be $100 billion smaller, a 2.4% decrease, without indirect international sources. In 2007, there would be $240 billion fewer downstream purchases of manufactured goods, a 4.5% decrease. These figures can be further decomposed across types of downstream buyers, both geographically and by purchase size.

Figure 2 displays the geographic distribution downstream of international-trade related changes to buyer surplus in 1997 and 2007. Details from 1997 are shown in Panel A and details from 2007 are shown in Panel B. Figure 2 displays the change in downstream surplus as a percentage of downstream expenditures. In 2007, California, New Jersey, and Texas all show an approximately 5% gain in downstream surplus. In contrast, the inland states of Wyoming, Montana, and Nebraska show approximately half the gain in surplus, with all three under 3%. Similarly, smaller buyers disproportionally benefit from the growth in wholesaling, as they are more likely to source from a wholesaler.

Different forms of wholesalers also differentially profit from international sourcing. Specifically, the largest wholesalers derive much more of their sales and operating profits from facilitating indirect international sourcing. Table 12 computes the aggregate changes in operating profits for three sizes of wholesalers, the largest 99th percentile of wholesalers by sales, the middle 90th to relative to the outside option.
99th percentile, and the bottom 90th percentile. In 1997, by limiting indirect international trade, the smallest wholesalers benefit with operating profits rising 6%, as some downstream buyers switch from using internationally sourced products to domestically sourced products. The largest wholesalers see a 50% decrease in operating profits as they are no longer able to source products from abroad and are not completely able to offset the loss in sales with domestically sourced products. The results from 2007 follow the same pattern, but are larger in magnitude. The smallest wholesalers see a 12% gain in operating profits, while the largest wholesalers face a 60% decline.

7.2 Counterfactual 2: Allowing Wholesaler Entry/Exit

This counterfactual offers an extremely simplified view of competition, with all wholesalers taking one of three configurations, either as a local wholesaler with only domestic sourcing, a globalized wholesaler with only international sourcing, or as a hybrid wholesaler with both international and domestic sourcing. In this scenario, the international-only wholesalers exit the market; they are no longer able to source materials. The hybrid wholesaler no longer has to pay the market positioning costs of international distribution, but loses sales from their earlier internationally sourced products.

Combining the data with this model’s estimated parameters, domestic source-only wholesalers are the smallest, with the lowest fixed entry costs and low expected qualities $\xi$ and high marginal costs $\nu$. These domestic-only wholesalers also tend to have small, extremely local distribution networks, with only one distribution outlet. Hybrid domestic-international wholesalers have the largest fixed entry costs, but the highest expected qualities and lowest marginal costs. These hybrid wholesalers also frequently have large national distribution networks, with multiple geographically dispersed distribution points.

As there are two categories of remaining wholesalers, there may still be more than one equilibrium. For example, there may be one domestic wholesaler and two hybrid wholesalers, or three domestic wholesalers and one hybrid. This analysis chooses the equilibrium with the greatest number of hybrid wholesalers. As the hybrid wholesalers have higher expected qualities and lower marginal costs, such wholesalers can be considered large first-movers. In computation, I simulate market entry 30 times and use both the upper and lower bounds of fixed cost estimates.

Table 11 summarizes market outcome changes from indirect international sourcing. In the third set of columns in Table 11 that are labeled “Counterfactual 2,” I show aggregate changes in downstream surplus, wholesaler profits, and market size after allowing for simplified wholesaler entry. International trade leads to increases of $360-380$ billion in buyer surplus in 1997 and over $540-580$ billion in 2007. This is double the first counterfactual that limits wholesaler entry/exit. Market forces drive out the best wholesalers (i.e. those that had both domestic and internationally sourced products). However, the free entry condition allows more domestic-only wholesalers to enter the market, partially compensating for the loss of wholesalers that source globally.

\footnote{Alternative results are calculated with equilibria that provide for the greatest number of domestic only wholesalers. While different in some of the wholesaler count statistics, overall surplus results are roughly similar.}
7.3 Alternative Scenario: Wholesaler Technology

In Appendix D, I consider a second scenario that measures aggregate gains in the wholesaling industry from 1997 to 2007, i.e. the inter-temporal gains from wholesaler technology. Downstream buyers in 2007 will no longer buy from the set of wholesalers from 2007, rather they will buy from the set of wholesalers using wholesaling technology from 1997. Summarizing my findings, changes in wholesaler technology and sourcing provide a net yearly gain of $200-300 billion in total surplus, offsetting a $200 billion loss from increases in wholesaler market power.

8 Underlying Mechanisms Interpretation

While changes in the costs and benefits of international sourcing drive much of the observed evolution in the wholesaling marketplace, this paper does not directly address the underlying mechanisms. This section provides a preliminary analysis. First, I discuss changes to the outside option, directly sourcing from a manufacturer. Second, I provide preliminary data concerning the use of information technology in the wholesale sector.

All wholesaler quality estimates are relative to the outside option, as are wholesaler prices. If domestic manufacturing is declining in quality or availability, downstream buyers will naturally substitute towards foreign suppliers, which may only be accessible through indirect sourcing. Similarly, changes in relative manufacturer’s prices across sources may change the relative valuation of wholesaling versus direct sourcing. Further work, using both international trade data and domestic production data could provide new insights. Recent research (Bernard and Fort (2015) and Bernard, Smeets and Warzynski (2016)) and anecdotal evidence suggest that the rise in wholesalers may be due to a economy-wide trend in former manufacturing firms closing domestic production operations and only retaining design and distribution facilities. However, these single-brand importers are excluded in my data sample.55

55See Appendix E for further evidence.
While this paper is able to bound the costs and the returns to scale for both international sourcing and domestic investment (and their complementarity), it does not discuss what technology underpins this change. Figure 3 provides preliminary and suggestive evidence that innovations and expenditures on information technology (IT) may be driving these trends. This figure shows the share of investment on software (an important component of IT) in both the manufacturing and wholesale sectors. While investment shares increased at a similar rates from 1960 to 1995, the path diverged between 1995 and 2005. Today, software accounts for 13% of all investment by wholesale firms, but less than 5% of investment by manufacturers. This finding corresponds favorably to my data; however, showing causality requires further analysis and is part of a larger research agenda.

9 Conclusion

Wholesalers and intermediaries are critical to global and domestic supply chains. This paper establishes a set of facts regarding wholesalers in relation to their upstream sources and downstream buyers. The distribution of goods in the United States through wholesalers has substantially increased, with the very largest wholesalers both increasing their domestic distribution networks and sourcing more foreign products. These facts are combined with a demand model to estimate downstream user preferences for intermediated trade through wholesalers. Wholesaler market entry is endogenized to consider counterfactuals regarding changes in fixed costs and the complementarity of a wholesaler’s international sourcing strategy with their domestic distribution network. The data provides evidence of trade-induced market power, where counterfactual wholesaler concentrations and markups are lower in the absence of international trade. However, downstream buyers gain substantial surplus from the expansion of the wholesale industry, which more than offsets increases in wholesaler market power.

Largely, modern empirical industrial organization has had little to say about average economy-wide levels of competition (Berry, 2017), with discussion primary using cross-sectional analysis (Autor et al., 2017). This paper uses the tools of industrial organization, leveraging both demand and supply data to understand why competition is decreasing and the downstream welfare effects in a sector accounting for $6 trillion in gross sales. I find that globalization is a wedge that may allow for both (a) more market power and (b) widespread benefits. In the context of wholesaling, I find that the benefits dominate changes in market power. This result stems from both the observed data and the model’s estimated parameters; other industries, time periods, or contexts will provide different results.

This paper provides one of the first comprehensive empirical studies of wholesaling and the role it plays in combining global and domestic economies. However, there is wide scope for both extending this framework and examining various assumptions. In terms of expansion, future work could use a model of intermediation with heterogeneous demand and place wholesalers in a tractable general equilibrium framework to consider aggregate surplus changes. Alternatively, additional work should consider changes in upstream manufacturing. Gains are all relative to sourcing directly from a manufacturer. Increases in difficulty in sourcing from a manufacturer (both domestically and internationally) can offset gains from wholesaling. This paper also leads to questions that examine the boundary of the firm: should a manufacturing firm expand domes-
tic distribution networks, or outsource to a wholesaler? Finally, this paper highlights the fruitful and productive work possible at the intersection of industrial organization and international trade.

Appendix (For Online Publication)

A Data Sources and Construction

A.1 Data Used

I bring together a variety of censuses and surveys conducted by the United States Census Bureau, Department of Transportation, and Department of Homeland Security covering international trade, domestic shipments and both the manufacturing and wholesale sectors. I use the Census of Wholesaling Trade, Census of Manufacturers, Longitudinal Firm Trade Transaction Database, Commodity Flow Survey, and the Longitudinal Business Database, from 1992 to 2012.

The Census of Wholesale Trade (CWH) collects data every five years on the entire universe of wholesale establishments, subdividing wholesalers by both type and ownership structure. In particular the CWH divides wholesale establishments into merchant wholesalers (MW) and manufacturers sales and branch offices (MSBO). As this paper considers wholesalers that are independent from manufacturers, I exclude MSBO and other similar establishments from analysis. However aggregate census statistics may not distinguish between these two establishment forms and overestimate the wholesaler market presence. Notably, distribution centers owned by downstream buyers, such as those by large retail chains are systematically excluded from this census.\footnote{The second largest building in the United States by usable space is the Target Import Warehouse in Lacey, Washington. However I assume that such buildings are classified as retailers and not wholesalers, with Target operating as the final destination.}

This dataset is central to the analysis and provides administrative data on operating costs, merchandise purchases, total sales, goods sold, and buyer types.\footnote{The biggest drawback of this data is the lack of quantity data. I will explicitly account for this in the model and estimating equations by considering units in terms of producer prices.} Wholesale industries distributing products with sales consisting of more than 50% non-manufactured goods are excluded. This includes certain petrochemical segments distributing crude oil and all agricultural and mining sectors. Data from 1992 and 2012 are not directly comparable to data from 1997-2002, due to changes in industry classification systems. (The 1992 data uses the Standard Industrial Classifications and 2012 data uses a revision of the NAICS system.)

The Census of Manufactures (CMF) aggregates data every five years on the universe of manufacturing establishments. This extensively used dataset provides information on a range of values, including total shipments and various operating and capital expenses. I focus on the value of shipments in producer values. This database helps in calculating the total domestic absorption of manufacturing products as well as the share of goods shipped directly by manufacturers. As with the CWH, the CMF lacks explicit quantity data for the vast majority of industries (notable exceptions include cement, concrete, and steel).

The Commodity Flow Survey (CFS) is conducted every five years and collects data on a random selection of shipments for a set of establishments. This data is collected for both wholesale and manufacturing establishments and is used to construct crosswalks between manufacturing and wholesale sectoral designations. Additionally the micro-data includes statistics on the origin, destination, and value of individual shipments as well as export status.

The Longitudinal Firm Trade Transaction Database (LFTTD) tracks and links imports and exports by product at the firm level. This database catalogues all import and export transactions...
by date from 1992 onwards in terms of both value and quantity. Tying all the datasets together, the Longitudinal Business Database provides a way to link individual establishments from the CWH, CMF, and CFS at the firm level, as well as linking these firms with trade data from the LFTTD. The process of merging these databases and further details are reported below.

A.2 Census of Wholesale Trade (CWH)

The US Census Defines a wholesaler in the 2007 North American Industry Classification System (NAICS) as:

The Wholesale Trade sector comprises establishments engaged in wholesaling merchandise, generally without transformation, and rendering services incidental to the sale of merchandise. The merchandise described in this sector includes the outputs of agriculture, mining, manufacturing, and certain information industries, such as publishing.

The wholesaling process is an intermediate step in the distribution of merchandise. Wholesalers are organized to sell or arrange the purchase or sale of (a) goods for resale (i.e., goods sold to other wholesalers or retailers), (b) capital or durable non-consumer goods, and (c) raw and intermediate materials and supplies used in production.

Wholesalers sell merchandise to other businesses and normally operate from a warehouse or office. These warehouses and offices are characterized by having little or no display of merchandise. In addition, neither the design nor the location of the premises is intended to solicit walk-in traffic. Wholesalers do not normally use advertising directed to the general public. Customers are generally reached initially via telephone, in-person marketing, or by specialized advertising that may include Internet and other electronic means. Follow-up orders are either vendor-initiated or client-initiated, generally based on previous sales, and typically exhibit strong ties between sellers and buyers. In fact, transactions are often conducted between wholesalers and clients that have long-standing business relationships.

This sector comprises two main types of wholesalers: merchant wholesalers that sell goods on their own account and business to business electronic markets, agents, and brokers that arrange sales and purchases for others generally for a commission or fee.

I focus on the first type of business, merchant wholesalers, which are further described as:

Merchant wholesale establishments typically maintain their own warehouse, where they receive and handle goods for their customers. Goods are generally sold without transformation, but may include integral functions, such as sorting, packaging, labeling, and other marketing services.

In addition, I omit three types of wholesalers, first those that are classified as Manufacturer’s Sales and Branch Offices (MSBO), those that are classified as own-brand importers and markets, and firms classified as agents/electronic markets. This specifically excludes what Bernard and Fort (2015); Bernard et al. (2016) consider former manufacturers that may have transitioned from
domestic manufacturing into foreign manufacturing and domestic distribution. If these firms are included as wholesalers, the wholesale shares of distribution increases even more dramatically.

For clarity, I’ve reproduced the selected portions of the Economic Census form from 2007 for NAICS 42319 - Electrical Goods Wholesalers in Figure 4 (forms from 1997 and 2002 are similar are publicly available). In question 19, I exclude firms that are classified as “14: Own-brand importer and marketer”, “20: Manufacturers’ sales branch or office”, “41-48: Agent, broker, or commission merchant”, “49: Electronic market”, or “77: Other broker or agent”.

Wholesalers are classified according to their five-digit NAICS code. A market is defined as all downstream buyers that buy and sell from these five-digit NAICS codes. For example, Code 42161 refers to wholesalers participating in the resale of “Electrical Apparatus and Equipment, Wiring Supplies and Construction Material”. While establishments may appear to belong to multiple codes, this project only considers the Census-designated code. Future research projects may further explore multiple-industry wholesalers. Firms may own establishments in multiple NAICS wholesale sectors. For these firms I divide up the foreign imports of these firms proportionally by purchased good value between these sectors.

Sales are aggregated considering the wholesaler’s purchase cost from their upstream source, net of export sales, and correcting for inventory adjustments. Prices are in manufacturers dollars and computed using the ratio between the sales to downstream buyers divided by upstream purchases by the wholesalers. Wholesale industries that derive more than 50% of revenues from products that are not manufactured are removed from analysis. These industries pertain primarily to mining and agricultural products. Additionally, NAICS sector 42471 and 42472 dealing with petroleum and petroleum products are removed, as are NAICS sectors 42481, 42482, and 42494 that deal with beer, wine and tobacco products. Petroleum products are removed due to the the industry taking a unique form due to the ownership and distribution of pipeline networks. Alcohol and tobacco products are often regulated at the wholesaler level by individual states. Some states do not allow for direct sourcing by downstream retailers and force the usage of wholesalers, rendering my model of wholesaling spurious.

A.2.1 Wholesaler Prices

Wholesaler prices are systematically denoted in producer prices. Therefore a wholesaler price of $1.3 implies that it costs $1.3 to indirectly buy $1 manufactured output (at the “factory gate”).

Wholesalers prices $p_w$ are constructed as follows:

$$p_w = \frac{\tilde{p}_w q_w}{\tilde{p}_m q_m},$$

where $\tilde{p}_m$ and $\tilde{p}_w$ represent the price paid by the wholesaler to a manufacturer and the price paid by a downstream firm to a wholesaler respectively. Variable $q_m$ represents the quantity purchased from a manufacturer, and $q_w$ represents the quantity sold by a wholesaler. In practice, quantity data is unavailable for most industries, so $p_m q_m$ is approximated by

$$C_m = p_m q_m,$$

Appendix - 4
where $C_m$ represents the expenditures of a wholesaler on manufactured goods. Similarly

$$R_w = \tilde{p}_w q_w,$$

where $R_w$ represents the revenue of a wholesaler. In Figure 4, $C_m$ corresponds to question 16(b) and $R_m$ corresponds to question 5(a).

I clean the data so wholesaler inventory changes are netted out, thus:

$$p_w = \frac{\tilde{p}_w}{\tilde{p}_m}.$$

As estimation requires a normalization, I set $\tilde{p}_m = 1$, so wholesaler prices $p_w$ are all relative to producer prices $\tilde{p}_m$. I explore robustness to this price definition in Appendix B.3, where I allow differentiated buyers to face different wholesaler prices.

In addition, I require operating cost data to derive relative markups in stage $t_1$, this corresponds to question 16(b) in Figure 4.

A.2.2 Wholesaler Sales Data

Wholesaler sales data is broken down by product origin by merging the LFTTD and CWH on firm-level characteristics. First, total sales are derived from the line item referring to “Sales and operating receipts.” Purchases from manufacturers are derived from the line referring to “Purchases of merchandise for resale.”

Data from the LFTTD denotes the imports by country of origin. Countries are divided into two categories using the World Bank’s World Development Indicators Database from 1997. Sources with per-capita gross domestic product (GDP) over $10,000 are categorized as high-income sources. Sources with per-capita GDP under $10,000 are classified as low-income sources. The cut-off county in my database is Slovenia, all countries richer than Slovenia are thus high-income sources. Due to extensive literature highlighting the pass-through nature of Hong Kong’s economy (Feenstra and Hanson (2004)), imports from Hong Kong and Macau are re-classified as Chinese imports.

As the World Bank estimates are not complete, I manually categorize a small subset of countries. Afghanistan, Iraq, Kosovo, Myanmar, Nauru, Sao Tome and Principe, South Sudan, Somalia, and Timor-Leste are classified as low income countries. San Marino is classified as a high income country. Overseas territories of the UK, Netherlands, and France are classified according to their parent country’s status (see Gibraltar, Curacao, and St. Martin/Sint Maarten).

Wholesaler purchases of domestic manufactured good are computed by subtracting imports from total merchandise purchases for resale. Finally, sales are adjusted to only consider domestic buyers. I subtract the percentage of sales and purchases that are used for export shipments. This export data is collected directly on the CWH forms. Additionally there are a subset of wholesaler firms that participate in multiple NAICS wholesale sectors. I allocate imports proportionally by the cost of goods sold between the multiple sectors.
A.3 Outside Share (Direct Sourcing) Data Construction

Both the summary statistics in Section 2 and the estimation routine in Section 4, require the construction of the total downstream market size and the share of the downstream market not served by US based wholesalers (the outside option). As wholesalers in the Census of Wholesale Firms (CWH) and and manufacturing producers in Census of Manufacturers (CMF) use different classification systems, a series of NAICS Wholesale to NAICS Manufacturers code concordances are used. See Ganapati (2015) for an overview of the process. In addition, the Import-Export Database (LFTTD) uses the Harmonized System (HS) of good classification and the Commodity Flow Survey (CFS) uses the Standardized Classification of Transported Goods (SCTG). Ganapati (2015) also uses the micro-data in the CFS and the LFTTD to provide concordances between the various NAICS, HS and SCTG codes at different levels of aggregation.

Total domestic absorption is computed as:

\[
\text{Total Domestic Absorption} = \text{Domestic Production} + \text{International Imports} - \text{International Exports}.
\]

Data on domestic production originates from the CMF as the sum of all domestically manufactured products. Data on international imports and exports originates from the LFTTD. For domestic wholesalers in the LFTTD, values are deflated by average wholesaler markups over manufacturer prices. This produces “total domestic absorption” in terms of producer’s prices. Since manufacturers and producers are not modeled in this paper, these prices are considered fixed. Alternative computation uses the CFS for domestic production and international export data.

Similarly domestic absorption accounted by wholesalers is computed as:

\[
\text{Domestic Wholesaler Absorption} = \text{Domestically Sourced Wholesaler Shipments} + \text{Wholesaler Imports} - \text{Wholesaler International Exports}.
\]

The first two components are computed using the combination of the CWH along with the LFTTD. The CWH reports total shipments and total exports, the LFTTD reports the total imports of a firm. Wholesaler international exports are computed using the self-reported CWH figure for total exports, alternatively the LFTTD may also be used.

Table 1 aggregates these statistics across the entire sample. See the main text for further analysis and a summary.

A.4 Detailed Wholesaler Statistics

**Figure 5: Distribution of Buyers**

Figures in real 2007 dollars.

**A.5 Distribution of Buyer Types**

I present an additional fact that describes the time evolution of buyer types in the Commodity Flow Data.

**Fact 6** *The distribution of buyer types has slightly skewed towards larger shipments over time.*

One hypothesis explaining the shift towards wholesaling is the spread of “just in time” manufacturing and supply practices. These business models forgo a small number of large deliveries for a larger number of smaller shipments. This provides downstream buyers with more flexibility and reduces inventory costs. In aggregate, such practices would imply that there is a shift towards smaller order sizes. If wholesalers are more adept at shipping smaller orders, then this may induce a shift of buyers switching to wholesalers. However, this has not occurred, as shown in Figure 5. Downstream buyers have slightly increased the average size of their orders over
A.6 Geographic Differentiation

In lieu of a continuous distance measure, this project discretizes downstream buyer location by US states, which are each located in 4 regions and 9 divisions. This project considers three distinct levels of distance with regards to the downstream buyer, wholesaler that are located in the same state, wholesaler located in the same census division and wholesalers located in a different census division. Figure 6 displays these divisions.

An alternative approach that would allow for tractable computation would be to map distance directly to distance indicator variables. This would prevent issues from considering the distance from New York to Connecticut differently than the distance from New York to New Jersey, due to Census division classifications. Instead of considering buyers that are within the same census division or region, the alternative would be to consider other states within pre-specified distance bands. For example, distance band 1 for New York would include all wholesalers in states that are reachable within 4 hours (250 miles) and distance band 2 would include all wholesalers in states that are within 8 hours (500 miles). Preliminary results show that estimates in Sections 5

---

58 A related fact shows that the geographic distribution of buyers has not significantly changed over the same time period.
59 The District of Columbia is redefined as a state for this project.
and 6 are largely consistent and the aggregate estimates in Section 7 are similar. However, the geographic breakdown is slightly changed, with the surplus gains due to intermediation slightly rising in small New England and South Atlantic States (in particular Rhode Island and Delaware) and slightly falling in rural Mountain States (Wyoming and Montana). The primary restriction here is the lack of computing power, enabling full estimation.

A.7 Case Study Details

In Subsection 2.1, I described a chemical wholesaler Univar. A slide detailing their business plan is presented in Figure 7.

B Demand Systems

This section provides micro-foundations for the indirect downstream profit functions used in Section 3. This provides support for both the two-stage demand system and allows for simple extensions. While this specific toy demand model provides micro-foundations for the exact demand structure presented in the main paper’s model, it is slightly generalizable, while still providing the needed structure. There are two critical elements, first requiring a single-input invertible production function and second requiring that the expectation of the marginal cost is sufficient for the wholesaler’s decision in the last demand stage (in period $t_4$).

B.1 Downstream Profit Maximization (1st Demand Stage)

To highlight downstream buyers choices of purchase quantity before the realization of idiosyncratic match shocks, consider a hypothetical downstream buyer. Assume that these downstream

\[^{60}\text{The logic here closely follows Hausman et al. (1995), switching the buyer’s problem to consider a producer’s profit maximization.}\]
buyers produce output using a single input, such that output $q = x$, where $q$ is the single input. Downstream buyers face constant elasticity of substitution (CES) demand for $x > 0$ units, with elasticity $\sigma > 1$ and demand-shifter $\eta > 0$. Additionally suppose there are fixed cost of production $f$ drawn from some distribution $F(\cdot)$.

First, I solve the firm’s problem disregarding the fixed cost. Demand take the form:

$$x = \eta p^{-\sigma}$$

Under such a CES demand framework, these downstream buyers charge markup $\mu$ which is a function of the elasticity of substitution $\sigma$:

$$\mu = \frac{\sigma}{\sigma - 1}. \tag{1}$$

This markup is invariant of the demand shifter $\eta$. The optimal price, $p^*$, charged by such a downstream buyer is product of the marginal cost of production $mc$ and the markup $\mu$:

$$p^* = mc \cdot \mu. \tag{2}$$

This price can be plugged back into the demand equation, solving for the optimal $q^*$:

$$x^* = \eta (\mu \cdot mc)^{-\sigma}. \tag{3}$$

Since the production function is one-to-one with the input, $q^* = x^*$. However, this assumes that downstream buyer marginal cost $mc$ is known. In the two-stage decision, downstream buyers must choose $q^{**}$ in a first period, only with knowledge of the possible distribution of $mc$. Then in the second period downstream buyers choose $p^{**}$ to clear the market. Solving through backwards induction, conditional on $x^{**}$, a downstream buyer chooses $p^{**}$ such that:

$$p^{**} = \left( \frac{x^{**}}{\eta} \right)^{-1/\sigma} \tag{4}$$

Then in the first stage, a wholesaler solves:

$$\max E [(p(x) - mc) \times x] \tag{5}$$

Plugging in values, iterating expectations of marginal cost, and taking first order conditions:

$$\pi(x) = x \left( \frac{x}{\eta} \right)^{-1/\sigma} - x E[mc] \tag{6}$$

$$\pi'(x) = \frac{\sigma - 1}{\sigma} \left( \frac{x}{\eta} \right)^{-1/\sigma} - E[mc] \tag{7}$$

Setting the first order conditions to zero and solving for $x^{**}$:

$$x^{**} = \eta (E[mc] \mu)^{-\sigma}. \tag{8}$$

$$= q^{**} \tag{9}$$

Appendix - 11
Where the last equality comes from the linear production function. This two stage demand provides for the same prices and quantities as before, however allows for uncertainty in the realized marginal cost.

If the demand shifter $\eta$ comes from some underlying distribution $N(\cdot)$, then the distribution of $q^*$ will come from this same distribution scaled by $(\mu \cdot mc)^{-\sigma}$.

Revisiting fixed cost $f$, expected profits are:

$$E(\pi) = E((p^{**} - mc) q^{**}) - f = \tilde{\pi} (E(mc)) - f$$

Where $\tilde{\pi}$ is an increasing function in terms of the expected marginal cost. Production only occurs if $\tilde{\pi} - f > 0$.

Aggregate downstream profits are decreasing function of marginal cost, thus a reduction in marginal costs increases downstream profits. The second stages demand decision involves choosing the optimal wholesaler to reduce this marginal cost. Additionally, these profits are a function of the fixed cost $f$; lowered marginal costs imply that more firms will be able to enter the market. Aggregating across the draws for downstream demand $\eta$ and the fixed costs $f$, this produces a mass of buyers $M_q$ that demand $q$ units. If $E(mc)$ falls, then the mass of $M_q$ will shift upwards. In my model $E(mc)$ is directly related to $E(U)$, the expected utility of indirectly sourcing from a wholesaler.

### B.2 Downstream Cost Minimization (2nd Demand Stage)

The indirect downstream profit function can be micro-founded through a simple cost minimization function for a downstream buyer. Suppose the cost of directly sourcing $q$ units is:

$$C_{direct} = q p_0 F(q)$$

Where $p_0$ is the per-unit cost and $F(q)$ is the per-unit overhead cost of setting up purchases for $q$ units. Suppose the indirect cost of sourcing $q$ units is:

$$C_{indirect} = q p_1$$

Where $p_1$ is the per-unit cost. For simplicity, suppose there isn’t an overhead cost. The logarithm of per-unit costs are then:

$$\log \left( \frac{C_{direct}}{q} \right) = \log (p_0) + \log \left( \frac{F(q)}{q} \right)$$

$$\log \left( \frac{C_{indirect}}{q} \right) = \log (p_1)$$

As long as downstream profits or utility are a function of the difference in per-unit costs, then the estimating equation (??) is appropriate.

---

Note that $\sigma > 1$. 

Appendix - 12
B.3 Quantity discounts

Business to business transactions often take a form where the sale price is a function of the quantity purchased. While estimated model does not directly account for this, a simple modification allows for quantity discounts to be easily added, without changing the implication of the model. Suppose that wholesaler price $p$ depends on the purchased quantity $q$ through discount factor $d(q)$ and a mean price $p$:

$$p_q = p \times d(q).$$

The discount function $d(q)$ simply is a schedule that multiplies some baseline price conditional on the purchase quantity $q$.

Simplifying the mean utility $\delta_q$ from equation (2) for any wholesaler selling to a buyer purchasing $q$ units produces:

$$\delta_q = \alpha \log p_q + f(q) + \xi$$

Where $f(q)$ represents the different preferences for wholesalers depending on purchase quantity $q$. Substituting the function for price:

$$U_q = \alpha \log p + \alpha \log d(q) + f(q) + \xi$$

Instead of recovering $f(q)$, estimation now recovers $\tilde{f}(q)$. In terms of buyer surplus calculations and market entry estimates, results are essentially unchanged. In terms of marginal cost estimates, similar logic prevails, and this paper computes a mean marginal cost, with industry-year fixed effect netting out buyer compositional changes. However for counterfactuals, I assume that this discount structure $d(q)$, through $\tilde{f}(q)$, is invariant. That is prices $p_q$ can only change through $p$ and not through $d(q)$, which will remain fixed.

B.4 Constant Elasticity of Substitution

The choice between wholesalers is modeled as a discrete choice decision and is micro-founded above. This modeling assumption is used both for tractability and realism, even though the majority of international trade research uses a constant elasticity of substitution demand system. However, there is a nice link between CES demand systems and the discrete-choice logit demand systems, as first described by Anderson et al. (1992) and elaborated by De Loecker (2011).

Assume that downstream product demand takes the form:

$$D(p) = \left(\frac{p}{P}\right)^{-\rho} \xi Y P = (p)^{-\rho} \xi Y \frac{P}{P^{1-\rho}}$$

Where $Y$ is total spending, $\xi$ is a demand shifter, $\rho$ is the elasticity of substitution, and the price index $P$ takes the form:

$$P = \left(\int \xi p^{1-\rho}\right)^{-\frac{1}{\rho}}$$
Wholesaler profit maximization takes the following form:

\[ \pi = \max_p (p - c) D(p), \]

which \( p \) denoting the price and \( c \) denoting wholesaler marginal cost. Assuming monopolistic competition, the optimization is as follows:

\[ D(p) = -(p - c) D'(p) = \sigma \frac{(p - c)}{p} D(p) \]

\[ p = c \frac{\rho}{(\rho - 1)} \]

So then higher/lower prices due to \( \xi \) only operate through its correlation to \( c \). Then wholesaler revenues \( R \) are:

\[ R = (p)^{1-\rho} \xi \frac{Y}{P^{1-\rho}} \]

Taking a log transform of the wholesaler revenue function produces the relationship:

\[ \log R = (1 - \rho) \log p + \log \xi + \log \frac{Y}{P^{1-\rho}} \quad (18) \]

Now since revenues are related to market share \( s \) and total market size \( Y \) as \( R = sY \), equation (18) can be rewritten as:

\[ \log s = (1 - \rho) \log p + \log \xi - \log P^{1-\sigma} \]

This estimating equation is almost identical to the logit estimating equation, with \( \alpha^p = (1 - \rho) \). The difference between these models, as noted by Anderson et al. (1992), is clearly in the economic interpretation, but the use of log prices forces identical substitution patterns. Note this model is not directly used in the empirical application, rather I use an aggregation of a nested logit framework. Further work can show this is equivalent to a two-level nested-CES demand aggregated across a variety of heterogenous downstream buyers. Both the two-level nested structure of demand and the heterogenous downstream buyers produce substantially more complex aggregate substitution patterns between wholesalers allowing much richer analysis. Critically, the difference between my model and most international trade papers is on the supply-side. Firms do not compete monopolistically, they are allowed to exert variable market power.

B.5 Demand Estimation

B.5.1 Discrete Choice Estimation Routine

Estimation follows a Generalized Method of Moments technique in the vein of Petrin (2002) and matches both aggregate national market shares and moments derived from the micro-level data.\(^\text{62}\)

Assuming away buyer heterogeneity and allowing for one level of nests (the full model follows Bresnahan et al. (1997) and allows for two non-nested levels of nests), I can derive the standard

\(^{\text{62}}\)Estimation proceeds sequentially, starting with demand estimation before moving to estimating the marginal cost and market entry parameters.
Berry (1994) estimation equation:

\[ \log s_{w,n} / \log s_0 = \delta_{w,n} + \sigma_n \log s_{w,n|n}, \]  \hspace{1cm} (19)

where \( s_0 \) represents the share of the outside option, sourcing directly from a manufacturer.\(^{63}\)

With buyer heterogeneity, the aggregate market share equation is more elaborate:

\[ \log s_{w,n} = \log \sum_{j \in J} \left( s_{0|j} \cdot s_{w,n|j,n}^\sigma \cdot \exp \left( \delta_{w,n,j} / (1 - \sigma_n) \right) \right) \mu_j \]  \hspace{1cm} (20)

Variable \( s_{0|j} \) represents the share of direct sourcing from manufacturing by buyers of type \( j \) and \( s_{w,n|j,n} \) represents the conditional share of a wholesaler \( w \) selling in nest \( n \) to customer \( j \). With downstream buyer heterogeneity, alongside wholesaler heterogeneity (that is different wholesalers serve different markets), the demand system provides for flexible substitution patterns and greater variety in markups.

In practice the estimation uses a finite number of buyer types \( j \), each with overall mass \( \mu_j \). Mean utility \( \delta_{w,n,j} \) can be decomposed \( \delta_{w,n,j} = \delta_{w,n} + \tilde{\delta}_{w,n,j} \). The first component is common across all downstream buyers and the second is specific to downstream buyers of type \( j \). Solving for \( \xi_{w,n} \), equation (20) is operationalized with one level of nests as:

\[ \xi_{w,n} = \log s_{w,n} - \log \sum_{j \in J} \left[ s_{0|j} \cdot s_{w,n|j,n}^\sigma \cdot \exp \left( \frac{\tilde{\delta}_{w,n,j}}{1 - \sigma} \right) \right] \mu_j - \alpha_j^p \log p_{w,n} + \alpha_j^{\text{I}_{w,n}} + \alpha_j^{\text{q}_{w,n}} + a_{w,n} \alpha_j^a \]  \hspace{1cm} (21)

Where \( \delta_{w,n} = \xi_{w,n} + \alpha_j^p \log p_{w,n} + a_{w,n} \alpha_j^a \). This defines a contraction mapping from \( \mathbb{R}^N \to \mathbb{R}^N \). By recursively solving for \( \xi_{w,n} \), I can solve this system of equations. Multiple levels of nests simply generalize this setup. Unlike the most general form in equation (20), the vector of parameters for unobservable coefficients is set such that \( \alpha_j = \alpha \) for all \( j \in J \).

In practice, this contraction mapping is the lengthiest step, as it is difficult to parallelize and requires 3 days of processing time the confidential census computing cluster. Alternative computation methods such as Mathematical Programming with Equilibrium Constraints (MPEC) are similarly slow as they require equality constraints for all 600,000 firms to be individually computed and checked.

**Aggregates Shares** Using observed market shares, a candidate parameter estimate \( \theta \), observed prices \( p \) and downstream market characteristics, estimation computes \( \xi_{w,n}(\theta) \) for each wholesaler. As shown in Section 4, \( \xi_{w,n} \) is uncorrelated with a series of instruments \( z \), so the identifying restriction is

\[ E(\xi_{w,n} z_{w,n}) = 0 \]

whose empirical analogue is \( Z'\xi(\theta) \), where observations are stacked by wholesaler. This set of assumptions will serve to pin down the price coefficient \( \alpha \) and substitution \( \sigma \).

\(^{63}\)If I assume that the unobserved parts of \( \delta_{w,n} \) are mean zero, I can run a linear regression and recover \( \xi_{w,n} \). However, this means that a wholesaler based in New York will face the same demand in California as in New York, thus the model without buyer heterogeneity is a baseline for the full model.
Micro-Level Moments  To pin down the coefficients for quantities and geographic indicators, estimation uses a series of moments that use estimated data and compare them with various facets of the survey data. In particular, the estimation routine matches the shares of within metro-area, within state and within Census region wholesale shipments along with wholesale shipment shares by shipment size. I denote the vector of moments produced by the data as $m_{\text{data}}$ and the estimated moments as $m(\theta)$.

Moment Function  Estimation obtains the parameter estimate $\hat{\theta}$ from minimizing the following criterion equation:

$$\hat{\theta} = \arg \min_{\theta} G(\theta)^{\prime} W G(\theta),$$  \hspace{1cm} (22)

where

$$G(\theta) = \begin{bmatrix} Z^{\prime} \xi(\theta) \\ m_{\text{data}} - m(\theta) \end{bmatrix}$$

and $W$ is a weighting matrix. First stage identification uses the identity matrix. But in a two-step procedure, estimation is iterated with the weighting matrix taking the form

$$W_2 = \left[ G\left(\hat{\theta}_1\right) G\left(\hat{\theta}_1\right)^{\prime}\right]^{-1}$$

with $\hat{\theta}_1$ denoting the estimates obtained using the identity weighting matrix.

By using the relation, $\delta_w(\sigma) = x_w \alpha + \xi_w$, estimation can be simplified. Thus conditional on $\sigma$, the GMM routine can use the estimation:

$$\hat{\alpha}_{IV}(\sigma) = \left(X^{\prime} Z \Phi Z^{\prime} X\right)^{-1} \left(X^{\prime} Z \Phi Z^{\prime} X\right)^{-1} \delta_w(\sigma; \alpha_l, \alpha_q)$$

Then I can use a GMM estimator to find $\sigma$, $\alpha_l$ and $\alpha_q$ that minimizes:

$$J_w(\sigma; \alpha_l, \alpha_q) = \left[\delta_w(\sigma; \alpha_l, \alpha_q) - x \alpha_w(\sigma; \alpha_l, \alpha_q)\right]^{\prime} \Phi Z^{\prime} \left[\delta_w(\sigma; \alpha_l, \alpha_q) - x \alpha_w(\sigma; \alpha_l, \alpha_q)\right].$$

B.5.2 Demand Estimation

Formally, I identify the demand parameters $\alpha$ and $\sigma$ using a modification of Berry and Haile (2014). Define $X$ as the set of attributes defined in the first-stage of the entry game, before the realizations wholesaler quality $\xi$. This means that a wholesaler has chosen whether they will participate in globalized trade and what dimension their domestic geographic footprint takes. Define $Z$ as a set of variables that shift marginal cost, but not downstream buyer valuations of wholesaler products. Define $M(\alpha, \sigma)$ as a set of aggregate moments, such as the predicted share of local wholesale shipments, and where $M_d$ is the observed realization of these moments. I make the following assumptions:

**Assumption 1** For every parameter $(\alpha, \sigma)$ there is at most one vector $\xi$ such that $s_{w,n}(\xi_{w,n}, \alpha, \sigma) - s_{w,n}^0 = 0$ for all $(w, o) \in W$.

**Assumption 2** $E[\xi_{w,o}|Z, X] = 0$ for each $(w, t) \in W$

**Assumption 3** $E[M(\alpha, \sigma) - M_d] = 0$

These assumptions are standard from Berry et al. (1995) and Petrin (2002); a demand invertibility condition, an instrumental variable condition, and a set of aggregate moments. The
first condition allows us to invert the observed market shares, conditional on \( X \) and obtain mean valuation \( \delta_{w,n} \) for each wholesaler-product combination \( w,n \in W \).

Assumption 1, 2 and 3, along with the the structure imposed from the model and set of regularity conditions identify \( \xi_{w,n} \) with probability 1 and the function \( s_{w,n}(\chi) \) is identified on \( \chi \). Formally, even without assuming a functional form for \( s_{w,n}(\cdot) \), demand identification stems from a modification of Berry and Haile (2014) to allow for aggregate moments.

### B.6 Demand Robustness

I consider two robustness exercises regarding my demand specification; (a) I compress and expand my multi-level nested logit specification and (b) I consider parameter heterogeneity across product-markets. In general, I find that results are largely unchanged.

#### Multi-level Logit Demand

In Figure 8, I show a series of alternative nesting patterns for the error term \( \epsilon \). Panel (a) shows a classic nested bi-level logit, simplifying the approach in Goldberg (1995). The downside of this model is it implies the substitution between wholesaler types is stronger than between sourcing patterns, which the model in the main paper avoids. Panel (b) compresses the top nesting structure into the second nest. This implies that foreign-sourced products sold by multi-source wholesalers are similarly substitutable between foreignsourced products sold by single-source wholesalers and domestically-sourced products sold by multi-source wholesalers. Estimates from such a model are shown in Table A4. In general, this simplified model produces estimates slightly different from the baseline model, as the coefficient estimates \( \alpha \) change to rationalize the data to difference in \( \sigma \).

Future projects could further explore the nesting structure in Panels (b) and (c). However this would require better data on the direct import-share of manufactured goods not at the national level, but at the local (state) level. This variation on the state-level import shares

Additionally, all direct sourcing in lumped together in an outside option.
would help identify the substitution parameter $\sigma_{\text{direct}}$ that would govern the top-most nesting structure. However this current project aggregates all direct imports at the national level for a data-driven reason. The used import data often lists only the port of landing, not the final destination of an imported product. (As a hypothetical, a disproportionate number of auto parts land in New Jersey, relative to the share auto plants located in the state.) Further work and assumptions are required disaggregate to state-level shipments.

Regressions/Markets: 56
Fixed Effects, Controls: Year $\times$ Source; Source $\times$ Varieties

Notes: Results from a 2-stage least squares routine. Robust standard errors presented.

Parameter Heterogeneity In Table A5 I repeat the estimation of my model, however within each of my 56 product-markets, generalizing away from buyer heterogeneity and using 2-stage least squares estimation. This produces 56 estimates for the parameter vector $(\alpha, \sigma)$. I report the average of three critical values for my model and markup calculations, the price coefficient $(\alpha_p)$, and the two parameters governing substitution between nests $(\sigma_o$ and $\sigma_n$). Results are similar to my main pooled specifications.

C Markup Calculations

For simplicity in this Appendix, I assume one level of nests and derive markups when wholesalers exert market power. In terms of notation $Q_{w,n}$ denotes total sales by wholesaler $w$ selling in nest $n$, $s_{w,n|j}$ is the market share conditional on downstream buyer type $j$, $s_{w,n|j,n}$ is the same share also conditional on sourcing from nest $n$, $M_j$ is the mass of downstream buyer type $j$, and $p_{w,n}$ is the wholesaler’s price. Parameters $\alpha_p$, $\phi$, and $\sigma$ are recovered from demand estimation, and respectively reflect the price sensitivity, aggregate demand elasticity, and substitution elasticities.
I first differentiating the total market size with respect to the wholesaler margin:

\[
\frac{\partial Q_{w,n}}{\partial p_{w,n}} (p) = \sum_j \left[ \frac{\partial s_{w,n|j}}{\partial p_{w,n}} M_j (p) + s_{w,n|j} \frac{\partial M_j (p)}{\partial p_{w,n}} \right]
= \frac{\alpha p}{p_{w,n}} \sum_j M_j s_{w,n|j} \left( \frac{1}{1 - \sigma} [1 - \sigma s_{w,n|j,n} - (1 - \sigma) s_{w,n|j}] + \phi s_{w,n|j} \right) = \frac{\alpha p}{p_{w,n}} s_{w,n}
\]

The new variable \( s_{w,n} \) summarizes the portion of the demand elasticity that does not directly use any pricing-related terms.

Marginal cost \( c_w \) are as follows for a single product wholesaler:

\[
c_{w,n} = p_{w,n} + Q_{w,o} \left( \frac{\partial Q_{w,n}}{\partial p_{w,n}} \right)^{-1}
= p_{w,n} + Q_{w,o} \frac{p_{w,n}}{\alpha p s_{w,n}} = p_w \left( 1 + \frac{Q_{w,n}}{\alpha p s_{w,n}} \right) \frac{1}{1/\mu_{w,n}}
\]

I denote multiplicative markups as \( \mu_{w,n} \).

For a wholesaler, the price set for products originating from \( o \) can also have implications for the sales of products originating from \( n' \) where \( n \neq n' \):

\[
\frac{\partial Q_{w,n'}}{\partial p_{w,n}} (p) = \sum_j \left[ \frac{\partial s_{w,n'|j}}{\partial p_{w,n}} M_j (p) + s_{w,n'|j} \frac{\partial M_j (p)}{\partial p_{w,n}} \right]
= \frac{\alpha p}{p_{w,n}} \sum_j M_j s_{w,n'|j} (\phi - 1) s_{w,n|j} = \frac{\alpha}{h_{w,n}} s_{n',n}
\]

For a multi-product wholesalers sourcing from multiple origins/selling in multiple nests \( n_1, n_2, \ldots \), consider the matrix of partial derivatives of sales of each sold with respect to to the prices of both the same product and other products sold:

\[
\Delta = \begin{bmatrix}
\frac{\partial Q_{w,n_1}}{\partial p_{w,n_1}} & \frac{\partial Q_{w,n_2}}{\partial p_{w,n_1}} & \cdots \\
\frac{\partial Q_{w,n_1}}{\partial p_{w,n_2}} & \frac{\partial Q_{w,n_2}}{\partial p_{w,n_2}} & \cdots \\
\vdots & \vdots & \ddots 
\end{bmatrix}
= \alpha \begin{bmatrix}
\bar{s}_{n_1,n_1} & \bar{s}_{n_1,n_2} & \cdots \\
\bar{s}_{n_2,n_1} & \bar{s}_{n_2,n_2} & \cdots \\
\vdots & \vdots & \ddots 
\end{bmatrix}
\begin{bmatrix}
1/p_{w,n_1} & 0 & \cdots \\
0 & 1/p_{w,n_2} & \cdots \\
\vdots & \vdots & \ddots 
\end{bmatrix}
\]

Solving the system of first order conditions implies that costs are:

\[
\begin{pmatrix}
c_{w,n_1} \\
c_{w,n_2} \\
\vdots 
\end{pmatrix}
= \begin{pmatrix}
p_{w,n_1} \\
p_{w,n_2} \\
\vdots 
\end{pmatrix}
+ \Delta^{-1} \begin{pmatrix}
Q_{w,n_1} \\
Q_{w,n_2} \\
\vdots 
\end{pmatrix}
\]

**Notes:** Market shares computed using the value of distributed goods in producer prices. Counterfactual 1 considers the wholesale market without wholesaler entry and exit. Counterfactual 2 allows wholesalers to enter the market. Mean results averaged over all markets. Figures in the last row differ from prior tables as they consider the unweighted mean across markets.

**Source:** Author’s calculations bases on US Census Data.

### D Alternative Counterfactual: Intertemporal Comparison

This second scenario considers the aggregate gains in the wholesaling industry from 1997 to 2007, i.e. the inter-temporal gains. Downstream buyers in 2007 will no longer buy from the set of wholesalers from 2007, rather they will buy from the set of wholesalers using wholesaling technology from 1997.

#### D.1 Counterfactual 1: Fixed Set of Wholesalers

What is the net benefit to downstream buyers and wholesalers due to aggregate market changes from 1997 to 2007? As shown in Section 2, total indirect sourcing has increased 35% in market share and 98% in real shipments. Section 5 parses out these gains through the demand model and attributes these gains to various changes in the types of wholesalers. This section assesses the net valuations of these changes by including both downstream buyer surplus and wholesaler profits.

Table A6 computes a variety of market outcomes by placing the universe of 1997 wholesalers in 2007. The first column lists a variety of relevant market outcomes, the number of wholesalers present, the number of wholesalers per market, the total market size for intermediate manufactured goods in producer prices, the change in downstream buyer surplus, the change in wholesaler profits, the sum of the changes in surplus and profits, and finally mean wholesaler market share (across sectors). The second column presents baseline data with the set of wholesalers from 2007, facing the demand from 2007.64

The third column of Table A6 considers the first counterfactual. The set of wholesalers from 1997, along with their attributes, are placed in their corresponding markets in 2007. In this counterfactual, wholesalers aren’t allowed to change their market position, but rather only their markups. As the number of wholesalers is larger in 1997, the number of wholesalers increases substantially in the counterfactual. However, these wholesalers are of lower quality, higher price,

64These figures are taken directly from the data.
and lack the domestic distribution reach and internationally sourcing ability of wholesalers in 2007. The total downstream market size decreases 6.6% or by $360 billion and the wholesaler share of this market decreases by 15%. Analogously, the surplus of downstream buyers decreases by $380 billion.

In 2007, the total size of the market is much larger, accounting for 10 year of economic growth. As the both the entry of wholesalers and the investment in wholesaler attributes are restricted, remaining wholesalers are able to increase their profits by $150 billion. By offsetting the decrease in downstream surplus with wholesaler profits, total surplus decreases by $230 billion. As a frame of reference, this total figure is equivalent to 1-2% of 2007 gross domestic product. To further refine this figure, I allow for a simplified form of wholesaler entry in the next section.

D.2 Counterfactual 2: Allowing Wholesaler Entry/Exit

The counterfactual for this second scenario places wholesalers from 1997 in the 2007 marketplace. In this counterfactual there is only one type of wholesaler, wholesalers that are present in 1997, and thus does not require an equilibrium selection procedure. Potential wholesalers draw types, qualities, and marginal costs from the observed distribution of wholesalers in 1997. Wholesaler choose to enter if the expected profits from entry are greater then fixed costs and choose not to enter if expected profits are less than entry costs. Letting $N$ denote the number of wholesalers in the market, this implies the following two conditions must hold:

$$E_G \left[ \pi_{2007} (N + 1) \right] < 0$$
$$E_G \left[ \pi_{2007} (N) \right] > 0$$

The function $\pi_{2007} (N)$ computes the profits by placing $N$ wholesaler draws of $(\xi, s, l)$ from the distribution $G(\cdot)$ for wholesalers that were present in 1997. The expectation is then computed over this distribution $G(\cdot)$. This simulates counterfactual surplus if wholesalers compete away their profits through a free entry condition.

The third column of Table A6 computes changes in market outcomes relative to the observed set of wholesalers in 2007. If wholesaling technology from 1997 were placed in 2007, downstream surplus would decrease by $240-330 billion. Wholesaler profits would remain unchanged as the free entry condition would force them to zero. The total downstream market for purchases would also decrease by $160-250 billion, or 3-4%. In terms of wholesalers, aggregate wholesale market share would decrease 5-6 percentage points, but the number of wholesalers would increase 20-60%. The individual market share of each wholesaler would also decrease by nearly \(1/3\), with a corresponding market concentration decrease.

E Factory-less good manufacturers

Recent research (Bernard and Fort, 2015; Bernard et al., 2016) and anecdotal evidence suggest that the rise in wholesalers may be due to a economy-wide trend in former manufacturing firms closing domestic production operations and only retaining design and distribution facilities. It appears the trends captured in this paper are largely independent and highly complementary to
the findings in Bernard and Fort (2015); Bernard et al. (2016). I address this research in three
different ways. First the residual quality term $\xi$ may capture a portion of this change. Second,
a large proportion of these former manufacturing firms are removed in the raw data. Third, the
evidence from international sourcing patterns is inconsistent with common formulations of this
outsourcing theory.

In the demand analysis the residual term $\xi_w$ captures the quality of a wholesaler $w$ that
rationalizes its price and market shares. If these wholesalers use contract manufacturing and these
contract manufacturers produce products with higher qualities, then the trend towards factory-
less good manufacturing is captured in this analysis. This is plausibly one of the underlying
mechanisms that deserves further study. However, it is not clear that these firms dominate the
data.

The Census of Wholesalers includes categorizations such as “own-brand marketer” and “single-
brand marketer”. If these wholesalers market only their own brand, then they are excluded
from the sample of wholesalers and treated as manufacturers. A possible example could be
the electronic firm Apple, that markets its own products but outsources manufacturing.\textsuperscript{65} In
addition, the analysis also excludes manufacturer owned sales and branch offices. These locations
exist to distribute products manufactured by a parent or sister firm. The elimination of these
establishments does reduce the observed growth in the wholesale sector, providing a conservative
approach to measuring the wholesaler market shares gains.

The behavior of the growth of these wholesalers takes a very particular form. As shown in
tables A1 and A3, the largest wholesalers are importing many more varieties from new foreign
sources and simultaneously increasing their distribution network within the United States. A
common formulation of the factory-less good manufacturer theory is that these manufacturers
close down production in the United States and move manufacturing abroad, with little to say
about designing new varieties for production or expanding local distribution networks. As
the benefit from wholesaling primarily derives from both sourcing new international destination,
not just moving producing overseas, and expanding domestic distribution, it is unclear that the
shift to factory-less production is driving the entirety of the trend towards wholesaling.

Finally, while this trend may be new for some firms, with Apple closing manufacturing lines
in the United States and outsourcing manufacturing to Foxconn in China, such ‘factory-less’
producers have existed for a long time. Historically when IBM produced personal computers,
they did not produce all components sold with the IBM brand; the printer was simply a rebadged
Epson device imported from Asia.\textsuperscript{66}

\section*{F Endogenous Quality}

In the main model, quality deviations $\xi$ are exogenous. I propose a mechanism whereby $\xi$ is
endogenously chosen by firms. Suppose between Stage 1 and Stage 2, firms choose $\xi$. Call this
Stage 1.5. While theoretically easy to add, this stage presents estimation challenges and requires
a modified estimation technique. In particular, this restricts the parameters estimated in the
\textsuperscript{65}The exact categorizations of firms cannot be disclosed outside of the US Census Bureau, it is unclear where
firms such as Apple stand and the textual discussion is purely hypothetical.
\textsuperscript{66}The IBM 5152 printer was a version of the Epson MX-80 printer.
demand estimation stage. Instead of finding valuations for firm attributes \( a_{w,n} \), all attributes are subsumed in a single vertical quality dimension \( \xi \). Therefore now:

\[
\delta_{w,n} = \alpha p_{w,n} + \xi_{w,n}.
\]

### F.1 Model Changes

Now, firms choose market entry in two stages. First wholesalers choose their domestic distribution locations and between entering as firm with domestic sources, international sources or with both domestic and international sources. In the second stage firms choose the quality of their products, their internationally and domestically sourced varieties. This includes the variety of products a wholesaler offers as well as the consumer service provided by the wholesaler. In terms of the model, a firm must optimally choose \( \xi_{w,n} \) for both their domestically and globally sourced products.

Conditioning on a firm’s type and location choices, the model assumes wholesaler \( w \) optimally chooses \( \xi_{w,n} \) for each product \( n \in N_w \). In particular they must invest \( f_w(\xi) \) to receive product attributes \( \xi_{w,n} \), which realize in operating profits \( \pi_w(\xi_{w,n}) \) from equation (7). If a firm only participates in only domestic sourcing, they maximize the following problem by choosing their optimal firm quality \( \xi_{w,n} \):

\[
\max_{\xi_{w,D}} \pi_w(\xi_{w,D}) - f_w(\xi_{w,D}) \quad (23)
\]

If firms participate in both first-world global and domestic markets, a firm \( w \) must choose two parameters, \( \xi_{w,FH} \), where \( n = FH \) represents first-world imports and \( n = D \) represents domestically sourced products:

\[
\max_{\xi_{w,D, FH}} \pi_w(\xi_{w,D, FH}) - f_w(\xi_{w,D, FH}) \quad (24)
\]

For simplicity, I now present results involving a single firm only involved in domestic sourcing and suppress firm subscript \( w \) and product type subscript \( t \). Conditional on location choices (market entry), a firm’s first order maximization results in a first order conditions as \( \xi \) are both optimally chosen:

\[
\frac{d\pi(\xi)}{d\xi} = \frac{df(\xi)}{d\xi} \quad (25)
\]

Without any errors, this solution concept implies that any two ex-ante identical firms will choose the same \( \xi \). As firms are only differentiated on an extremely limited set of dimensions in the market entry stage, this setup will not fully rationalize the data. To better rationalize the data and account for the heterogeneity present in the world, the model allows for firm-specific investment cost shocks. Before wholesalers choose their market position, but after entering the market, each wholesaler receives shocks to the marginal costs of investing. Call these shocks \( \eta_\xi \).

Given these shocks, two ex-ante firms will no longer make the same investment choices and thus fully rationalize the observed data. Given a form for a time-varying investment function \( f(\cdot) \), parameterized by the vector \( \chi \), the econometrician can recover changes in the return to investment. In particular, in the context of wholesaling, are the returns to investing in domestic
and international quality differentially changing for large and small firms?

**F.2 Estimation**

In this model, unobserved downstream consumer valuations \( \xi \) are not exogenous shocks as in standard discrete choice models. They are the product of wholesale firm investments. This \( \xi \) is better written as \( \xi(a) \). This means that demand identification cannot identify \( a^\alpha a_{w,n} \). In this case, all fixed effect, \( a^\alpha a_{w,n} \), and \( \xi \) are all subsumed by the new measure \( \xi(a) \). \( \xi(a) \) is no longer residual quality, it is a complete measure of quality. Regardless, the coefficient \( \alpha^p \) can be identified as a cost shock hits a particular firm following their choice of \( a \) and \( \xi(a) \). In terms of \( \alpha^p, \alpha^l, \) and \( \sigma; \) they are partially identified off of aggregate moments. As \( \alpha^p \) is the only coefficient required to derive demand elasticities, estimation can proceed in a more restricted fashion.

Having made these assumptions, identification of this investment function proceeds directly from the first order conditions in equation (25). For any given company configuration \( a \) (that is conditional on a company type \( s \) and location choices \( l \)), assume that the fixed costs of market positioning are:

\[
f_{w}^a(\xi, \eta) = \left( \frac{\chi_1^a}{\chi_2} \eta_{w,\xi} \right) \exp(\chi_2^a \xi) + E_a
\]

The function \( f_{w}^a(\xi) \) measures the cost of investing in quality \( \xi \) for wholesaler of configuration \( a \). There are scalar fixed costs \( E_a \) and two parameters, \( \chi_1^a \) and \( \chi_2^a \). Finally there is a wholesaler specific shock \( \eta_{w,\xi} \). This structural investment cost shock is known to the firm, but not the econometrician.

Conditional on entry, a wholesale firm of configuration \( a \) seeks to maximize profits \( \pi_{w}(\xi) \) net of investment \( f_{w}^a(\cdot) \). As both \( \pi_{w}(\cdot) \) and \( f_{w}^a(\cdot) \) are smooth linear functions, computation of the optimal profits requires solving the firm’s first order conditions. Marginal investment cost are

\[
\frac{df_{w}^a(\xi, \eta)}{d\xi} = \left( \frac{\chi_1^a}{\chi_2} \eta_{w,\xi} \right) \exp(\chi_2^a \xi)
\]

and marginal profits stem from the first derivative of equation (7) with respect to \( \xi \), \( d\pi_{w}(\xi) / d\xi \). As all the parameters in \( \pi(\cdot) \) are known, the optimal marketing costs in equilibrium solve:

\[
\frac{d\pi_{w}(\xi)}{d\xi} = \frac{df_{w}^a(\xi, \eta)}{d\xi} = \left( \frac{\chi_1^a}{\chi_2} \eta_{w,\xi} \right) \exp(\chi_2^a \xi).
\]

Taking the logarithm of this equation produces the following relationship:

\[
\log \frac{d\pi_{w}(\xi)}{d\xi} = \log \chi_1 + \chi_2 \xi + \log \eta_{w,\xi}.
\]

The relationship should be theoretically estimated by ordinary least squares, however the shock \( \eta_{w,\xi} \) likely is correlated with the choice of \( \xi \). This echoes the endogeneity problem with \( \xi \) and \( h_{w} \) in estimating equation (??). Estimation of \( \chi \) requires a shifter of \( \xi \) that is uncorrelated with \( \eta \). This leads to an assumption required for identification.

**Assumption 4** There exist \( Z_\eta \) such that \( E[\eta Z_\eta] = 0 \).
Thus, under this model’s demand and supply systems, investment cost parameters $\chi$ are identified.

What is a plausible exogenous shifter of $\xi$? Estimation could use a combination of two shifters, one using the timing of the game and the second using geographic differentiation. The first shifter uses logic similar to those of the cost shifters in the demand estimation. Wholesale firms are likely to choose higher levels of $\xi$ when similar wholesale firms in nearby geographically proximate, but unrelated markets choose higher levels of $\xi$. So the average $\xi$ in New Haven for importing chemical wholesalers can be used as an instrument for New Haven electronic wholesalers. The second shifter exploits the timing of the game, firms choose their attributes $a$ before investing in $\xi$, thus the number of firms of type $a'$ at the state, regional and national level shift the choice of $\xi$ independently of $\eta$.

In computation, $\pi_w(\xi)$ is not fully known by a firm before the investment decision $\xi$ is made. In particular there is an unobserved cost shock $\nu$ from equation (13) that shifts profits. I assume the distribution of $\nu$ is known and firms maximize their expected profit. To aid in computation, instead of numerically integrating over $\nu$, simulated draws of $\nu$ are used to compute $E[\pi_w(\xi)]$.

For simplicity, I omit the expectation in what follows.

Investment function $f_{aw}(\cdot)$ is identified up to some fixed entry constant $E_c$. Following estimation of $\chi^1_a$ and $\chi^2_a$, this step also generate the distributions $G_{a}\eta(\cdot)$ for investment shocks of $\eta_{w,\xi}$. For notational simplicity denote $\xi_w^{*}$ as the optimal choice for firm $w$ with investment cost shocks $\eta$.

Second-stage net profits for a firm of configuration $c$ are

$$n_a(\eta) = \pi_{aw}^*(\xi^*(\eta)) - f_{aw}^a(\xi^*(\eta), \eta),$$

where $f_{aw}^a(\cdot) = f_{aw}(\cdot) - E_c$.

Note that $f(\cdot)$ is only identified up to some constant $E_a$, $f(\cdot)$ subtracts this constant. The function $n_a(\eta)$ is used in the next stage to identify this entry cost $E_a$. For tractability, I assume that fixed cost $E_a$ is not paid in this stage, as firms in this stage have already entered into the market and that an infinitesimal small investment in $\xi$ (that is $\xi \to -\infty$) will realize a investment cost of 0.

### F.3 Market Positioning Estimation

Table A7 presents estimation results for $\chi$, which parameterizes the relationship between fixed costs and product quality $\xi$. The table presents the results from two different regressions. The first column present the results for investment in quality regarding domestically sourced products and the second column presents estimates for investment in sourcing internationally sourced products. All regressions control for year, industry and the domestic distribution networks of firms. This estimation uses a simplified demand system with only nesting at the product-source

67The chosen functional form for $f_{aw}^a(\cdot)$ and the estimation equation (27) imply that $\chi_1 \eta$ is greater than zero, thus as long at $\chi_2$ is greater than zero, $f_{aw}^a(\xi^*)$ will be always greater than zero.

68Additionally, under a free entry condition for counterfactuals, estimates from this step are not needed to compute alternative equilibria. Due to free entry, firms will reenter until $\pi'(\xi) = F'(\xi)$. This step does matter for when the fixed costs of entry change, but market positioning costs are unaltered. (are vice versa) In particular this step is mostly critical for understanding the role of 'business' stealing arising from competition.

**Notes:** Robust standard errors do not reflect errors in demand estimates. See text for full regression specification.  
**Source:** 1997, 2002 and 2007 Commodity Flow Surveys, Censuses of Wholesalers and Manufacturers and Longitudinal Firm Trade Transactions Database.

The first three rows of Table A7 illustrate year-specific coefficients for $\chi_2$ from equation (27). These estimates measure the cost in investing in quality $\xi_{domestic}$ and $\xi_{international}$. The first column shows that it becomes more costly to invest in domestic sourcing quality over time. One interpretation would be that there are fewer domestic manufacturers, and thus it is more difficult to find new and better domestic sources. Coefficient $\chi_2^{domestic}$ increases 7% from 1997 to 2007. The second column shows that it has become less costly to invest in the quality of international sourcing, with $\chi_2^{international}$ decreasing 20% from 1997 to 2007. This may reflect both lowered trade barriers and increases in the quality of foreign manufactured good sources, both of which make it easier to increase the quality of imported products.

These regression estimates also reveal the degree of complementarity between investment in domestic and international sourcing. The fourth row reflects estimates for log $\chi_1$ for instances where wholesale firms participate in both domestic and international sourcing. The negative estimate in the first column shows that participating in international sourcing makes it slightly cheaper to increase the quality of the domestically sourced product. The opposite is true for participating in domestic sourcing, which makes it much more expensive to invest in the quality of the internationally sourced product.
