## **Abstract**

Working consistently through one's fifties and early sixties is key to attaining retirement security. However, workers also need access to retirement plans – so they can continue to accumulate resources – and health insurance – so they can avoid withdrawing assets in the event of a health shock. Yet, despite the fact that a large literature focuses on nontraditional jobs (i.e., jobs that often lack these benefits), it is unclear how older workers use these jobs. If some older workers end up in nontraditional work for much of the rest of their careers, then they likely will end up worse off financially. If, instead, older workers use nontraditional jobs only temporarily before returning to traditional work or as a bridge to retirement, then it is unlikely that their financial situation will substantially change. This paper uses the *Health and Retirement Study* to identify nontraditional jobs and relies on sequence analysis to explore how workers ages 50-62 use them. The results suggest that the majority of nontraditional jobs are used by workers consistently, and that fewer workers use these jobs briefly or as a bridge to retirement. In the end, the consistently nontraditional workers end up with less retirement income than other workers, even controlling for characteristics like education. Policymakers may want to consider policies like Auto-IRAs that ensure retirement savings vehicles are readily available to workers in nontraditional jobs.

## Introduction

While working consistently through one's fifties and early sixties is key to achieving retirement security, working – by itself – may not be enough. Workers in jobs that lack retirement and health benefits are at risk of a retirement income shortfall. Few households save for retirement outside of employer-sponsored plans, and poor health drains resources for those without health insurance. Yet, despite the increased focus on “nontraditional” jobs – jobs that usually lack these benefits – it is unclear how older workers use these jobs and how they might affect retirement security.<sup>1</sup> If some older workers end up in nontraditional work for much of their later careers, then they likely will end up worse off financially. If, instead, older workers use nontraditional jobs only temporarily before returning to traditional work or as a bridge to retirement, then it is unlikely that their financial situation will substantially change.

To gain a better understanding of the uses and impact of nontraditional jobs in workers' late-careers, this project follows workers from ages 50 through 62 in the *Health and Retirement Study* (HRS), and determines at each age whether they are in a traditional job, a nontraditional job, not working, or retired.<sup>2</sup> The next step is to use sequence analysis to group older workers who have similar employment patterns, calculate the share following each pattern, and compare the personal characteristics of each group. Finally, to evaluate whether these employment patterns predict retirement security, the project will use the employment groupings from the sequence analysis as explanatory variables in a regression analysis on the availability of retirement resources. The results will shed light on the ways in which older workers use nontraditional work, how the use of that work varies by socioeconomic status, and ultimately how it affects retirement security.

The remainder of the paper is organized as follows. The first section provides background on how older workers use nontraditional jobs late in their careers. The second section describes the data and provides details on how nontraditional jobs are identified in the HRS, and also offers a comparison to other estimates of the prevalence of these jobs. The third section describes the methodology behind sequence analysis as well as the regression formulation used, while the fourth section presents the results. The final section concludes that

<sup>2</sup> In practice, not working is defined as earning less than \$5,000 per year, unemployed, or out of the labor force (which includes disabled individuals).

just 26 percent of the sample works in a traditional job with benefits throughout their 50s and early 60s – this “ideal” pattern of employment is just not that common. Of the remainder, four patterns emerge: 1) those who retire well before age 62 (21 percent); 2) those who are only weakly attached to the labor force (16 percent); 3) those who work consistently, but in nontraditional jobs (11 percent); and 4) those who work consistently and mainly in traditional jobs, but with brief periods of nontraditional work or not working (26 percent). Importantly, the group that works consistently in nontraditional jobs ends up with roughly 20 percent less in retirement income than those in mainly traditional jobs. Ensuring that this group of workers has convenient savings vehicles at their jobs – potentially through programs like Auto-IRAs – is therefore an important policy goal.

## **Background**

Despite the possibility that nontraditional jobs could occur at any time in a worker’s late career, almost all research on how nontraditional work fits into late-career employment patterns has been focused on jobs that serve as a stepping-stone to ease the transition into retirement.<sup>3</sup> Johnson and Kawachi (2007) find that older workers who switch jobs near retirement are likely to end up in a nontraditional job that does not offer benefits, but also report greater satisfaction with those jobs, in part due to less stress and lighter physical demands. Some evidence also exists that workers use these lower-compensating jobs to gain flexibility in their schedules as they approach retirement (James, Swanberg, and McKechnie 2011). Indeed, Cahill, Giandrea, and Quinn (2011) find that more than 60 percent of older workers who left full-time career jobs moved to this sort of “bridge job.” In other words, this literature would suggest that using nontraditional jobs as a transition to retirement may be somewhat common.

A limited literature also suggests that some older workers use these jobs more frequently. Specifically, research shows that workers who were in nontraditional jobs for an extended period have difficulty transitioning back to traditional work (Fournier et al. 2011). For example, about one-fifth of temporary workers become trapped in a “precarious job carousel” where they cycle between bad jobs and no jobs (Barbieri and Scherer 2009; Fuller and Stecy-Hildebrandt 2015). However, it is unclear exactly how common this outcome is for older workers specifically.

---

<sup>3</sup> Quinn and Burkhauser (1990) and Ruhm (1990) provide early reviews of partial retirement and bridge jobs.

While researchers have not focused on how older workers use nontraditional jobs in their late-career working patterns, other work has used sequence analysis to investigate labor force participation at older ages more generally. For example, Calvo, Madero-Cabib, and Staudinger (2017) use sequence analysis to examine how workers' labor force status evolves in their 60s. Their analysis considers full- and part-time employment and non-employment to show that few workers follow the transition from full-time work to complete retirement at age 65. Instead, the retirement process is much more diverse and includes early and late retirement, as well as people who remain partly retired all the way up to age 70. However, their study does not consider the traditional or nontraditional nature of any jobs and does not focus on the 50s, a time of life when people should be working to prepare for a secure retirement.<sup>4</sup>

## Data

Given the lack of research on the use of nontraditional jobs throughout late careers, this paper uses the 1992 to 2016 waves of the *Health and Retirement Study* (HRS), a biennial longitudinal survey of older Americans to characterize workers' labor force patterns from ages 50 through 62 and to see how nontraditional work fits in. The sample consists of members of the Original HRS, War Baby, and Early Baby Boomer birth cohorts, for whom data on work history are currently available through age 62. Although the analysis seeks to follow workers from ages 50 to 62, to increase the sample size the paper also includes those entering the HRS at 52 and imputes these individuals' age 50 work status.<sup>5</sup> The sample is further restricted to respondents who live to at least 62, do not otherwise exit the HRS prior to 62, do not have missing demographic variables (described below), and work at least one time between ages 50-62. Within this sample, some people are missing information for individual waves – if this omission happens for three or more waves the individual is dropped from the analysis; if it is for two or fewer waves then their work status is imputed for the missing periods. The final sample consists of 4,174 respondents (see Table 1 for detail on the exclusions).

---

<sup>4</sup> Gustman and Steinmeier (2000) also examine patterns of full-time work, partial retirement, and complete retirement but do not use sequence analysis; their analysis is limited to the first four waves of the HRS, so the number of potential patterns is more manageable.

<sup>5</sup> All imputations are carried out using STATA's mi (multiple imputation) framework, as described in Halpin (2013).

Once the sample is identified, the next step is to identify each individual’s work status at each wave from ages 50 through 62. For the sequence analysis, each individual is assigned one of four statuses in each wave: 1) not working (but not retired); 2) retired; 3) working in a traditional job; and 4) working in a nontraditional job. Not working is defined as earning less than \$5,000 a year but not claiming to be fully retired.<sup>6</sup> “Retired” is defined as not working and classified as retired by the RAND labor force status variable. Among those who are working, the key distinction is between traditional and nontraditional work. The issue is how to define nontraditional work.

### *Defining Nontraditional Work*

Defining nontraditional work is complicated – an agreed upon definition does not exist, and different definitions yield vastly different estimates. Much of the existing literature has defined this type of work based on the nature of the relationship workers have with employers. Using this approach, researchers have come up with a wide range of estimates. The narrowest definitions of nontraditional work are limited to workers in the “gig economy” (e.g., Uber, Task Rabbit) or in short-term employment relationships.<sup>7</sup> These groups include just 1 percent and 2 percent of workers, respectively.<sup>8</sup> At the other extreme, the U.S. Government Accountability Office’s concept, which includes the self-employed and those in part-time jobs, covers 31 percent of the workforce.<sup>9</sup> In between these extremes is the definition of “alternative” work used by the Bureau of Labor Statistics (BLS) – which has received considerable attention through research by Katz and Krueger.<sup>10</sup> The BLS definition includes independent contractors and workers who are either with a temp agency, employed by a contract firm, or on-call. Under this definition, the prevalence of nontraditional work hovers around 10 percent. Another definition in between the two extremes is that of “1099 workers,” as used in a 2019 study by Collins et al. These workers are self-employed individuals who work for firms (i.e. freelancers and “gig”

---

<sup>6</sup> This definition also includes those who claim not to be working because they are disabled, unemployed, or otherwise out of the labor force.

<sup>7</sup> Short-term jobs are defined as expected to last less than one year.

<sup>8</sup> See Farrell and Grieg (2016); U.S. Bureau of Labor Statistics (2018); and Collins et al. (2019).

<sup>9</sup> U.S. Government Accountability Office (2015).

<sup>10</sup> Katz and Krueger (2016, 2019).

work) but do not fall under normal employment classification rules, and file 1099 tax forms. Using this definition, nontraditional work would account for 11.8 percent of the workforce.<sup>11</sup>

Regardless of how nontraditional jobs are defined, the common thread is that they often lack basic benefits, such as health insurance and retirement plans, and/or have volatile earnings and employment. For this reason, our analysis adopts a more direct measure of nontraditional jobs based on such job characteristics. Specifically, the analysis will define nontraditional work in two ways: 1) broadly as any job lacking both health insurance and retirement benefits; and 2) more narrowly as a job without these benefits that also has some measure of job instability.<sup>12</sup>

Given the variation in prevalence across the various definitions, it is useful to see how a definition based on job characteristics like benefits compares to the more employer-employee relationship definitions from the existing literature. To ensure an accurate comparison, the analysis requires a dataset with questions on both the worker-employer relationships used in the other definitions presented above, and job characteristics like the availability of benefits that are used in this paper. For this purpose, the BLS's *Current Population Survey* (CPS) is the best source.

For the comparison of the various definitions that exist in the literature to the one used in this paper, we first compute the share of workers ages 50-62 in 2017 who are in employer relationships under the standard BLS definition. Next, the share of workers in jobs without health insurance and retirement benefits is calculated – i.e., our broad “no benefits” definition of nontraditional work (unfortunately, the CPS does not have the right variables to get at the measures of instability used in the narrow definition). Under the BLS measure, 11 percent of workers in 2017 were in nontraditional jobs, compared to 20 percent under the broader no-benefits measure (see the solid bars in Figure 1, which also includes other definitions for additional context). The estimates in Figure 1 are for a single point in time. Figure 2 compares the two measures over 1994-2016, and it still finds a large and persistent gap.

---

<sup>11</sup> Collins et al. (2019).

<sup>12</sup> One potential problem with identifying health insurance being offered by an employer is that the line of questioning in the HRS only asks if individuals are covered by their employers' plan, not whether they are offered it. So married individuals with coverage through their spouse would look like they are not offered health insurance. Looking at the CPS, it turns out roughly 70 percent of married individuals with health insurance through their spouse were also offered it at their job – we assume that if a person's spouse has employer health insurance that they were offered coverage through their employer. This approach provides a conservative estimate of nontraditional work.

Given the considerable gap between the two definitions of nontraditional work, the question is: which does a better job of picking up the vulnerable workers that researchers are concerned with? It turns out, compared to the workers defined as nontraditional under the BLS definition, the additional workers picked up by the broader no-benefits definition tend to have shorter job tenure and lower socioeconomic status (see Table 2).<sup>13</sup> The basic issue is that the BLS definition includes many independent contractors, and those individuals tend to have been employed in that type of work for a while with relatively high incomes even though they may lack benefits.<sup>14</sup> By picking up many employees working without benefits instead of workers who lack benefits only because they employ themselves, the definition used in this paper and based on the presence of benefits picks up more vulnerable workers than the BLS measure, making it a better choice for this paper.

Given that the benefits-based definition used in this paper seems to appropriately capture vulnerable workers, it is worth exploring how the definition looks in the longitudinal data needed to do sequence analysis – the HRS. Reassuringly, the HRS data show that the percentage of workers ages 50-62 in jobs with no benefits is generally similar to that using the CPS data despite a noticeable difference early in the period (see the gray versus the red lines in Figure 3).<sup>15</sup> As noted above, the concern over nontraditional jobs stems not just from a lack of benefits, but also a lack of stability in earnings or employment. Some of the jobs that lack benefits will be stable, and these workers may be less vulnerable. So, the paper also uses a more narrow definition that takes into account job stability. This definition will count a job as nontraditional if it lacks benefits and: 1) has hours that are variable at some point during the job; or 2) if the worker is self-employed with no benefits and with no employees.<sup>16</sup> Under this definition, the percentage of jobs that are nontraditional falls from 16.9 percent to 7.6 percent, somewhat lower than the standard BLS definition of nontraditional workers.

---

<sup>13</sup> The *Current Population Survey May Supplement* does not ask earnings questions for all workers.

<sup>14</sup> Authors' calculation from the CPS. For example, the median tenure for an independent contractor ages 50-62 is 15 years, much higher than for the typical worker, and they have an average household income of \$85,000, similar to traditional workers under the BLS definition.

<sup>15</sup> The definition shown in Figure 3 defines nontraditional as lacking benefits. Another approach would be to use the longitudinal nature of the data to see if the job *ever* offered those benefits. Such an approach reduces the share of those in nontraditional jobs by 3-4 percentage points. This approach is not used as the default since it seems relevant that the person said the job was lacking those benefits in a given year.

<sup>16</sup> The study includes the self-employed with no benefits and with no employees as nontraditional work to capture those who run a small business or are independent contractors.

## Methodology

With each worker assigned a status as not working, retired, working in a traditional job, or working in a nontraditional job, the next step is to identify various patterns of work for ages 50-62 using sequence analysis. Then, the project turns to analyzing the relationship between these employment sequences and retirement resources using a regression analysis.

### *Sequence Analysis*

Sequence analysis is a relatively novel technique in the social sciences; its strength is that the outcome of interest is an individual's entire employment history rather than employment status or job transition at a given age. The goal of sequence analysis is to group together workers with similar employment statuses at similar times and in a similar order. Consider the hypothetical example below, which shows how three workers move between traditional work (T), nontraditional work (N), not-working (U), and retired (R).

Example 1. *Employment Sequences for Hypothetical Workers*

	Age						
	50	52	54	56	58	60	62
Worker A	T	T	N	N	T	T	R
Worker B	T	T	N	T	T	T	R
Worker C	T	T	N	N	N	U	R

In this example, the sequence analysis will likely group workers A and B together, because they both started as traditional workers, used nontraditional work temporarily before returning to traditional work, and then retired at the same age. The only difference is small: how long they experienced nontraditional work. That experience differs distinctly from the pattern for worker C, who moved from traditional to nontraditional work at the same age as A and B, and retired at the same age, but never returned to traditional work.

In more technical terms, sequence analysis compares all of the sequences for sample members and constructs a matrix of how different each sequence is from the others. The difference between sequences is based on the minimum number of modifications needed to transform one sequence into another. A modification can take one of two forms. The first form is a substitution in which the state of one sequence is changed to match the state from another

(e.g., changing work status at age 56 from nontraditional to traditional so that workers A and B have the same sequence). The second form is an insertion or deletion. An insertion occurs where a state is plugged into a sequence and every other state pushed back one wave to an older age. A deletion occurs when a state is removed and every subsequent state pulled forward to a younger age. Insertions and deletions typically happen simultaneously: a state is inserted and another state is deleted to preserve the number of observations.

To determine the difference between two sequences, the analysis follows the literature and uses optimal matching analysis (OMA). OMA requires that each substitution and insertion or deletion be assigned a “cost” to calculate the difference between sequences. The simplest way to calculate these differences would be to add up the number of substitutions and insertions/deletions – in other words to assign a uniform cost of one – but this approach has several disadvantages. Most notably, it does not recognize that some substitutions reflect much bigger changes than others – e.g., substituting a traditional job for a person who is not working at all may be a bigger leap than substituting a status of retired. Simply assigning substitution costs based on theories of which transitions are more likely to run the risk of being highly arbitrary, so this project uses an intuitive metric. Observed transition probabilities – transitions that are observed frequently in the data – e.g., from not working to retired – are assigned a lower substitution cost than those that are uncommon. Once substitution costs are assigned, this paper follows the approach commonly taken in the literature and sets the cost of insertions/deletions to one-tenth of the highest substitution cost.<sup>17</sup>

The end result of OMA is a so-called pairwise distance matrix, which contains the sum of the costs of all substitutions and insertion/deletions required to transform each sequence into another. To group similar sequences together, a Hierarchical Cluster Analysis is used to detect groupings among the individual sequences with respect to their pairwise distances.<sup>18</sup> The last step is to determine the number of groups for the analysis to detect. To choose the number of groups, the process was run assuming 2 through 12 groupings, with the final choice reflecting the

---

<sup>17</sup> Assigning the insertion and deletion cost to one –tenth of the highest substitution cost tends to create sensible sequence groupings (MacIndoe and Abbott 2004; Hollister 2009).

<sup>18</sup> Specifically, the project used Ward’s hierarchical clustering linkage criteria to group sequences that are similar to each other such that the groupings minimize the difference between sequences within the group and maximize the difference between sequences among the groups.

number that maximized the Caliniskin and Harabasz index such that the resulting sequences made theoretical sense.<sup>19</sup>

### *Regression Methodology*

With the sequences in hand, the next question is how individuals' employment patterns relate to their available retirement resources at age 62. The issue is that people experiencing different patterns of non-employment, retirement, traditional work, and nontraditional work in their 50s and early 60s will also have different initial characteristics that may cause them to fall into those sequences, and those initial characteristics are likely to affect their preparedness. For example, workers frequently doing nontraditional work may have less education and therefore contribute less to retirement accounts even when they have the resources. Failure to control for education would therefore exaggerate the negative role of a sequence showing frequent nontraditional work – i.e., these workers would indeed have less, but some of the effect would be due to their education level, in addition to the effect of the late-career work pattern captured by their sequence assignment. Conversely, if workers who are consistently in traditional jobs are also healthier initially, then their retirement preparation may be helped by low health spending in their 50s. Ignoring initial health would exaggerate the positive effect of a primarily traditional work sequence.

To analyze the effect of each of the identified sequence groupings on retirement preparedness, the paper estimates a regression in which the individual's assignment of a sequence group serves as the independent variable of interest. The regression also controls for demographic characteristics and initial health. The equation to be estimated is:

$$R_{i,62} = \beta_0 + \sum_{j=2}^K \gamma_j S_{i,j} + X'_{i,50} \beta + \delta H_{i,50} + \tau_i + \varepsilon_i \quad (1)$$

---

<sup>19</sup> The Caliniskin Harabasz index is a measure of the extent to which sequences within clusters are similar to one another and sequences across clusters are dissimilar (Cornwell, 2015). Specifically, the index is the ratio of the *between group* sum of squared differences to the *within group* sum of squared differences. Sequence analysis is vulnerable to claims that the results are the consequence of an ad hoc trial and error. To test the validity of the results, this paper used different cost assignments and dropped imputed respondents and achieved similar results. For critiques of sequence analysis and responses to those critiques, see Aisenbrey and Fasang (2010).

where  $R_{i,62}$  is the log of the individual's retirement income at age 62: defined benefit pension income, Social Security benefits, and annuitized defined contribution plan and other financial wealth.<sup>20</sup> The variable  $S_{i,j}$  is an indicator for whether person  $i$  was assigned to sequence group  $j$ . Therefore,  $\gamma_j$  is the percentage point change in the individual's retirement resources associated with being in sequence group  $j$  relative to the base sequence group, which is assigned as the one with the highest amount of traditional work. The vector  $X'_{i,50}$  contains demographic characteristics that could ultimately affect an individual's preparedness, like education, gender, race/ethnicity, and their age-50 marital status.<sup>21</sup> Finally,  $H_{i,50}$  is an index of the individual's initial health at age 50 that is based on objective measures, with higher values indicating worse health, whereas  $\tau_i$  enters year of sample entry fixed effects.<sup>22</sup>

The hypothesis is that, even conditional on the initial characteristics described, sequences containing primarily traditional work with little interruption will be associated with the higher retirement income at age 62. The next-highest sequence will occur where nontraditional work is used sparingly as a stopgap, followed by long spells of nontraditional work. The sequences with the lowest retirement income will be those associated with long spells of nontraditional work – in other words, weak attachment to the labor force – or very early retirement. This hypothesis means that relative to the base sequence of consistent traditional work, the coefficients  $\gamma_j$  will be increasingly negative for sequences as they move from mostly traditional work to mostly nontraditional work and finally to unattached.

## Results

This section first presents the results of the sequence analysis, before turning to the regression results.

---

<sup>20</sup> Social Security wealth is obtained based on RAND imputations that use Social Security administrative data. Defined-contribution and financial wealth are assumed to be annuitized at a rate consistent with private market data from ImmediateAnnuities.com.

<sup>21</sup> For those who are not observed at age 50, the closest wave to age 50 is used.

<sup>22</sup> In practice, eight health conditions and five limitations to activities of daily living are used: The health conditions are: 1) high blood pressure with medication; 2) diabetes with insulin; 3) cancer of any kind, seeing doctor; 4) activity limiting lung disease; 5) heart condition, taking medication; 6) emotional/psychological problems; 7) stroke with problems afterward; and 8) arthritis with medication. The limitations to activities of daily living involve needing help with: 1) bathing; 2) getting dressed; 3) eating; 4) using a map; and 5) walking.

## *Sequence Analysis*

The results show late-career employment patterns of HRS workers and how nontraditional jobs fit into those patterns. The sequence groupings were calculated for each definition of nontraditional work, the broad no-benefits definition and the narrower definition that includes both no-benefits and instability.

With the broad no-benefits definition of nontraditional work, five work patterns emerge (see Figure 4). The first two involve individuals who do not work consistently throughout their 50s and 60s. These individuals are either in an “Early Retirement” sequence with retirement in their 50s (21 percent of sample members) or are in a “Weak Attachment” sequence, with frequent spells of not working despite not retiring (16 percent). The next three sequences consist of people who work most of the time, and include sequences of work that are: “Mostly Nontraditional” (11 percent); “Mostly Traditional” (26 percent); and “All Traditional” (26 percent). The “ideal” employment pattern of working throughout one’s 50s and early 60s in a job with benefits is rare – less than a third of workers do it. Although somewhat surprising, the result does not seem to be an artifact of the HRS data used here; individuals in the *Panel Study of Income Dynamics* (PSID) from 1998-2010 showed almost the same low share of workers fitting the ideal pattern.<sup>23</sup>

With respect to how nontraditional jobs are used within those sequences, it turns out that the vast majority of nontraditional work is done by those who do it often – it is used less often as a bridge to retirement or a stopgap to unemployment. To illustrate, Table 3 shows the distribution of nontraditional jobs across these sequence groups – under the broad definition, 16.9 percent of all jobs are nontraditional. The table shows that 53.7 percent of all nontraditional jobs (9.1/16.9) are within the Mostly Nontraditional sequence. The comparable number is 11.0 and 25.7 percent for both the Early Retirement and Weak Attachment sequences, representing a total of 36.7 percent of all nontraditional jobs. The remaining 9.6 percent of nontraditional jobs fit into the Mainly Traditional sequence. Overall, older workers tend to fall into two very different groups: they use these jobs either often or only briefly.

---

<sup>23</sup> In that dataset, both retirement plans and health insurance were identified for a sample of 403 individuals ages 50-52 in 1998 (the same start wave as the War Baby Cohort in the HRS), who worked at least once, and who were observed continuously through 2010. In this sample, only 24.6 percent worked in a traditional job the entire time – remarkably similar to the number in the HRS. It seems that it really is not that common to be in a consistent, traditional job between ages 50 and 62.

Turning to the more narrow definition of nontraditional work (see Figure 5) – jobs with no benefits and less stability – the fundamental nature of the sequence groupings is unchanged, although a sixth group differentiates very early retirements from those who simply retire prior to age 62.<sup>24</sup> The main difference between the two definitions is intuitive – sequences involving nontraditional work are less common. Table 3 shows that the majority of nontraditional jobs are done by the small percentage of workers in the Mostly Nontraditional sequence, who use nontraditional jobs consistently throughout their 50s and 60s. And within the group doing mostly traditional jobs, fewer spells of nontraditional work exist under the narrow definition.

Tables 4 and 5. Respectively, highlight the demographics of older workers, by sequence group, at their first HRS observation, based on the broad and narrow definitions of nontraditional work. Since most nontraditional jobs are held by people who do them frequently, the focus is on this sequence group. This group appears more vulnerable than workers who are mostly in more traditional work arrangements, although the differences are not as extreme as one might expect given their continued work in jobs without benefits. For example, those who are in the Mostly Nontraditional sequence are 77 percent white, compared to 81 percent for those in the Mostly Traditional sequence. Similarly, 47 percent of those in the Mostly Nontraditional sequence have at least some college education, compared to 57 percent in the Mostly Traditional sequence. The share who are female, the marriage rates, and the number of health conditions are fairly similar between the two groups. Table 5 shows a similar conclusion when the narrower definition of nontraditional work is used.

It would be nice to understand why some people spend most of their late work lives in nontraditional jobs. Latent Class Analysis (LCA), which identifies unobservable subgroups within a population (See Box 1), shows that workers who spend most of their time in nontraditional work fall into three basic categories (see Table 6).<sup>25</sup> The first group is defined by a lack of education: 15.4 percent of the Mostly Nontraditional sample lacks a high school degree.

---

<sup>24</sup> The five-group cluster analysis result for the narrow definition of nontraditional work grouped together older workers who do not consistently work with those who are in nontraditional work all of the time. The six-group cluster analysis result separated this combined grouping.

<sup>25</sup> Three groups were chosen because the Bayesian Information Criterion (BIC) was lower for three groups than for either two or four groups. An LCA analysis was also conducted for the more narrow definition of nontraditional work and is available upon request. Overall, the results were similar, with one group composed disproportionately of high school dropouts, the second of individuals in dual-earner relationships, and the third of individuals without an earning spouse. The main differences were that, under the narrow definition, the less-educated group included some high school graduates and the group without an earning spouse included no married individuals at all.

The second is defined by their marital status: the 35.5 percent of workers in this sequence are married and have an earning spouse. For these two groups, working in mostly nontraditional jobs makes sense. The less educated group likely has trouble finding good work, and the group with an earning spouse likely has much less need to hold a job with benefits. It is not as clear why a third group ends up in nontraditional work is a not as clear. This group defined by not having an earning spouse, but otherwise appears fairly similar to the typical worker – albeit more likely to be non-white, slightly less educated, and slightly less healthy. Future work should investigate how workers who appear to be demographically similar end up in different work patterns in their early careers, but this question is beyond the scope of the current paper.

*Box 1. Description of Latent Class Analysis*

Latent class analysis (LCA) is a tool that allows researchers to identify relationships among observed categorical variables as a function of some unobserved grouping. The analysis starts with the observation that within the population, the observed variables are not independent. For example, within the group of workers in the Mostly Nontraditional group, being a high school dropout may tend to occur together with being nonwhite. The goal of latent class analysis is to group the observations so that within each group, or “latent class,” the observed categorical variables are locally independent. That is, being a high school dropout and nonwhite are both explained by some unobserved third variable, for example the level of economic advantage.

Conditional on an assumed number of classes, LCA outputs two sets of estimates: 1) the share of the population within each class; and 2) the conditional probabilities of having a given value for each observed variable within each class. These parameters are estimated by Maximum Likelihood Estimation. The second output – the conditional probabilities – have a special interpretation within LCA since they represent an association between the class and the observed characteristic. That is, if one class is comprised disproportionately of high school dropouts who are nonwhite, then that class can be viewed as more economically disadvantaged than the other.

*Regression Results*

The regression results are presented in Table 7 and are largely intuitive. Focusing on the first column, which uses the broad no-benefits definition, workers who do mostly traditional work and use nontraditional jobs only sparingly have 5.5 percent lower retirement income at age 62 than those who work consistently in traditional jobs. More dramatically, those who use nontraditional jobs frequently have 26.2 percent lower retirement income, suggesting a long history of these types of jobs can be detrimental to retirement preparedness. Indeed, being weakly attached to the labor force actually has a slightly smaller effect, a 14.6-percent reduction, suggesting that – with respect to retirement income – working consistently in nontraditional jobs

is no better than working inconsistently. The effect of early retirement in the regression is insignificant, perhaps because the early retirement sequence is comprised mainly of people who go from traditional jobs to retirement and are perhaps relatively well prepared. The other coefficients in the regression are consistent with expectations, with being a person of color or in poor health associated with lower available retirement income, and more educated and married are associated with more income.

The second column shows the results when the sequences are based on the narrow definition of nontraditional work, which incorporates job instability. The effect of nontraditional work is similar – workers in mainly traditional jobs with infrequent bouts of nontraditional work have 8.2 percent lower retirement income at 62 than those in only traditional jobs, while those consistently in nontraditional jobs have income that is 17.2 percent lower. With respect to the other sequences, weakly attached sequences again result in significantly lower retirement income – 24.2 percent less – than a sequence composed of entirely traditional work, although this time the effect is more negative than those consistently in nontraditional work. The coefficients on early retirement – including the “Very Early Retirement” sequence unique to this definition – are both insignificant. Again, the demographic coefficients are intuitive.

## **Conclusion**

Despite the increased focus on nontraditional jobs in the popular press and academic literature, how older workers use these jobs and their effect on how well older workers are prepared for retirement has not been studied. Yet, working consistently in a job with benefits throughout ones 50s and early 60s is likely key to retirement preparedness. This paper uses sequence analysis to characterize how older workers use nontraditional jobs in their late-careers and then regression analysis to see how these patterns relate to their available retirement income.

The results suggest that a third or less of workers have the “ideal” sequence of late-career employment: a traditional job with benefits consistently from ages 50-62. Many retire early or have brief bouts of not working or nontraditional work and, worse, many have a weak attachment to the labor force or are in nontraditional jobs consistently. The regression results show that having a sequence that only briefly contains nontraditional work decreases income by roughly 6 percent to 8 percent, depending on the definition used, but doing nontraditional work consistently has a much larger effect of 26.2 percent to 17.2 percent. Indeed, the effect of

consistent nontraditional work is similar to being only weakly attached to the labor force. This finding illustrates the importance of ensuring that all workers have access to convenient retirement savings vehicles – similar to state auto-IRAs – so that workers whose jobs do not offer benefits do not end up as vulnerable in retirement as people who have worked much less.
