

# The Impact of Social Insurance on Household Debt \*

Gideon Bornstein<sup>†</sup>      Sasha Indarte<sup>‡</sup>

July 11, 2023

## Abstract

This paper investigates how the expansion of social insurance affects households' accumulation of debt. Insurance can reduce reliance on debt by lessening the financial impact of adverse events such as illness and job loss. But it can also weaken the motive to self-insure through savings, and households' improved financial resilience can increase access to credit. Using data on 10 million borrowers and a quasi-experimental research design, we estimate the causal effect of expanded insurance on household debt, exploiting ZIP-code level heterogeneity in exposure to the staggered expansions of one of the largest US social insurance programs: Medicaid. We find that a 1 percentage point increase in a ZIP code's Medicaid-eligible population increases credit card borrowing by 0.56%. Decomposing this effect in a model of household borrowing, we show that increased credit supply in response to households' improved financial resilience fully accounts for this rise in borrowing and contributed 32% of the net welfare gains of expanding Medicaid.

# 1 Introduction

Unsecured debt is an important tool that households rely on to smooth their consumption—not only across time but also across states of the world. For example, of the 4 in 10 US adults that report anticipating difficulty in meeting an unexpected \$400 expense, credit cards are the most-cited tool that they expect to rely on.<sup>1</sup> And when experiencing an income shortfall, 43% of US households report turning to borrowing, including credit cards.<sup>2</sup> When unsecured debt functions as a de facto source of insurance, changes to social insurance could significantly affect households' desire and ability to access credit.

Whether social insurance crowds in or crowds out household debt is theoretically ambiguous. The total effect depends on the strength of competing channels. On the one hand, improved access to social insurance can reduce households' reliance on debt to cope with adverse shocks such as job loss and illness, crowding out debt. On the other hand, credit demand and supply channels may also work in the opposite direction. Social insurance can increase the demand for debt by weakening the precautionary savings motive. Additionally, when social insurance makes households less likely to default, this reduction in risk can make creditors more willing to lend. Expanded insurance can improve households' financial resilience, which can in turn increase access to credit.

This paper sheds new light on how credit markets shape the impact of social insurance on household debt and welfare. We first estimate the causal effect on credit card borrowing of the expansion of Medicaid under the Affordable Care Act (ACA), one of the largest changes to the US social safety net in recent years. We find that a 1 percentage point increase in the share of a ZIP code's population eligible for Medicaid increases revolving credit card balances by 0.56 percentage points. Next, we develop a heterogeneous-agent model in which households face both income and medical expenditure shocks while having the ability to borrow and default on unsecured debt. Simulating the expansion of Medicaid in the model, we find that increased credit supply is fully responsible for the overall increase in household debt. Moreover, the credit supply response to expanding Medicaid accounts for 32% of the net

---

<sup>2</sup>Source: 2016 SCF.

welfare gain.<sup>3</sup> Our findings demonstrate that expanding social insurance can *crowd in* the supply of unsecured debt and that this improvement in credit access can lead to first-order welfare gains. We conclude that policymakers may significantly underestimate the benefits of social insurance programs if they overlook potential increases in credit access spurred by improved financial resilience.

Our focus on health insurance is motivated by the importance of Medical expenses as a source of financial distress for US households. In a survey of bankruptcy filers, 29% named medical bills as the reason for their bankruptcy (Himmelstein, Thorne, Warren and Woolhandler, 2009). In a recent survey of US residents, unexpected medical bills ranked first in terms of what kind of expenses they worry most about being able to afford, ahead of rent or mortgages, transportation, and food.<sup>4</sup> Health expenditures constitute a large and growing share of US GDP, reaching 18.3% in 2021.<sup>5</sup> Despite the importance of health expenses, they have received less attention in the macroeconomics literature compared to other sources of risk such as job loss and housing.<sup>6</sup>

We begin by estimating the causal effect of Medicaid eligibility on a variety of credit outcomes using credit bureau data on 10 million US borrowers over 2010-2021 in a continuous difference-in-difference (DID) analysis. We exploit granular variation in the *size* of eligibility changes induced by states' staggered expansions of Medicaid under the ACA. This variation arises from two sources. The first comes from states' pre-expansion Medicaid policies. Expanding Medicaid under the ACA required states to implement a common set of eligibility requirements. As a result, ZIP codes with similar distributions of income saw larger increases in eligibility if their state previously had stricter requirements. The second source of variation comes from within-ZIP differences in the distribution of income among low-income households. Eligibility increased more in ZIP codes that had more low-income households clustered between the pre- and post-expansion income eligibility thresholds.

---

<sup>3</sup>Our measure of net welfare reflects improvements stemming from the financial benefits of the Medicaid expansion (net of the tax costs of expansion). We do not model either mortality or utility as a function of health. Therefore, our welfare estimates do not reflect gains from improved health or reduced mortality.

<sup>4</sup>Source: Kaiser Family Foundation Health Tracking Poll (February 2020). Link: <https://www.kff.org/health-costs/poll-finding/data-note-public-worries-about-and-experience-with-surprise-medical-bills/>.

<sup>6</sup>Notable exceptions include Livshits, MacGee and Tertilt (2007); Chatterjee, Corbae, Nakajima and Ríos-Rull (2007); Attanasio, Kitao and Violante (2010); De Nardi, French and Jones (2010).

Our difference-in-difference estimator compares credit outcomes before and after expanding across ZIP codes with bigger versus smaller changes in eligibility. The within-state variation in the impact of expansions makes it possible to use state-time fixed effects in our analysis, which help account for other unobserved state-level policy changes that may have coincided with expansions and also affected credit outcomes. Identification requires that the change in eligibility is not correlated with other shocks coinciding with the expansion.

We find that expanded Medicaid eligibility increases credit card borrowing. A 1 percentage point increase in eligibility leads to a 0.13 percentage point increase in the share of households with at least one credit card and raises revolving credit card balances by 0.56 percentage points. Consistent with a positive credit supply response, we document that increased eligibility also increased credit limits and overall reduced credit card utilization. On the demand side, we also find that the number of credit card inquiries rose. In line with our financial resilience hypothesis, we show that expanding Medicaid also reduced severe forms of default (debt in collections), minor forms of default (delinquency) remained stable despite the rise in borrowing, and credit scores increased.

We then construct a heterogeneous-agent model in which households have access to credit card debt. Households face idiosyncratic income shocks as well as idiosyncratic expenditure shocks. They can save using a risk-free asset or borrow via credit card debt, which they can decide not to repay. Households incur debt both by choosing credit card borrowing and as a result of experiencing expenditure shocks that they are unwilling or unable to cover on impact. The interest rate paid on credit card debt is endogenous and depends on the probability households do not pay their owed debt.

The nature of credit card debt in our model is a hybrid of one-period and long-term debt used in the literature on consumer bankruptcy and sovereign debt.<sup>7</sup> When households are not delinquent, they must roll over their debt that period. That is, credit card debt must be repaid in full to avoid delinquency. However, households have the option not to repay their debt and enter a delinquent state. In that state, they cannot take on more debt before paying their current debt in full.<sup>8</sup> Households in a delinquent state get a stochastic haircut

---

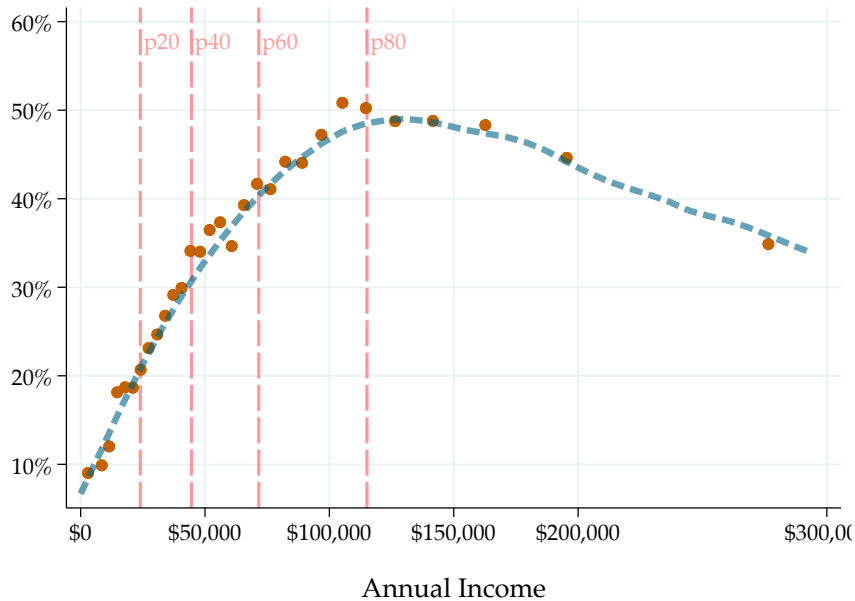

<sup>7</sup>Notable examples of such models include [Chatterjee et al. \(2007\)](#); [Livshits et al. \(2007\)](#); [Arellano \(2008\)](#) for short-term debt and [Hatchondo and Martinez \(2009\)](#); [Chatterjee and Eyigungor \(2012\)](#) for long-term debt.

<sup>8</sup>While households cannot choose to take on more debt in the delinquent state, uninsured expenditure shocks

on their debt, which can help them exit the delinquency state. Since financial intermediaries who hold claims on delinquent debt are not repaid immediately, the pricing of debt has a long-term component to it.

The delinquency option on debt allows us to capture a key aspect of the data. The relationship between having unpaid/revolving credit card balances and income follows an inverse U-shape, as displayed in Figure 1. Less than 25% of households with annual income below \$25,000 have any credit card debt. This share rises to 50% for households with an annual income of \$100,000 and declines as household income rises. Delinquency, together with endogenous credit supply, restricts low-income households' access to credit.

**Figure 1: Share of Households with Credit Card Debt**

*Notes:* This figure plots a binscatter of the share of households with a non-zero amount of unpaid (i.e., revolving) credit card balances. Data come from the PSID (2011–2019). Annual income is in real 2019 USD.

Capturing the inverse U-shape relationship between income and credit card debt is important for studying policies that target low-income households, such as Medicaid. This is because means-tested social insurance policies generally target households whose default risk limits their credit access. By reducing this risk, social insurance can lead to better credit access. We model Medicaid as a policy that covers a fraction of households' expenditure shocks, add to households' total debt.

where eligibility for Medicaid depends on household income.

Health insurance policies affect the aggregate level of credit card debt through three channels. First, the direct effect of more generous health insurance is increasing households' disposable income. Households can achieve the same consumption levels while borrowing less. In addition, the expanded insurance reduces delinquency rates, leading to an increase in debt levels. Overall, the direct effect of health insurance on credit card debt is ambiguous.

The second channel is through credit demand. Health insurance affects demand for credit even if credit terms remain unchanged. Lower medical expenditures reduce households' precautionary savings motive and, as a result, increase their borrowing. However, households are more likely to repay their debt in the future. This results in a higher level of *expected* repayment, which discourages borrowing. These competing forces mean that the effect of the credit demand channel is also theoretically ambiguous.

The third channel is the credit supply channel. The reduction in delinquency rates leads to lower interest rate spreads in equilibrium. Lower interest rates induce households to take on more credit, leading to an increase in the aggregate level of credit card debt.

While we ground our model in the context of health insurance, the economic channels we study can arise in many other contexts. Our model and approach can be readily adapted to study the impact of other types of social insurance (unemployment insurance, minimum wages, disability insurance, and so on). Additionally, a similar model could be used to study how changes to insurance/risk exposure affect sovereign and corporate credit outcomes. Quantitatively, which channels dominate in equilibrium may vary with context.

Our model abstracts away from several features of health— notably, "physical" health that enters the utility function, price-sensitive demand for health services ("moral hazard"), and correlations between income and health expenditures. As we discuss in detail in Section 3, this likely makes our counterfactual analysis conservative regarding the welfare and borrowing responses.

Our model predicts that expanding Medicaid led to a 5% overall increase in credit card debt. We find that the direct channel has a small impact on the aggregate level of credit card debt and that the credit demand channel reduces the aggregate level of credit card debt substantially. Together, these two channels decrease credit card debt by 7.7%. The overall increase

in credit card debt is solely due to the credit supply channel, which increases aggregate credit card debt by 12.4%.

We use our model to study the welfare benefits associated with the expansion of Medicaid. We find that the policy is equivalent to a permanent increase in consumption of 47 basis points. Of the welfare gains, 32% is a result of the reduction in interest rate spreads households face on their debt. This result suggests policymakers should take into account the effect social insurance has on credit supply. Disregarding the credit supply channel could substantially underestimate the welfare gains of social insurance programs.

**Related Literature:** This paper contributes to several strands of literature by bringing a new macroeconomic perspective to the effects of social insurance. First, our model builds on the macroeconomic literature on consumer bankruptcy and default (e.g., [Chatterjee, Corbae, Nakajima and Ríos-Rull, 2007](#); [Livshits, MacGee and Tertilt, 2007](#); [Mitman, 2016](#)). This literature focuses on the drivers of default—in particular, the role of bankruptcy policy. We study a policy that does not directly target bankruptcy or default: public health insurance. This policy can reduce default and increase both credit access and borrowing.

Second, we add to a large macroeconomic literature on heterogeneous agent models with uninsurable risk ([Bewley, 1986](#); [Aiyagari, 1994](#); [Huggett, 1993](#)). This literature highlights how precautionary savings play a key role in shaping the macroeconomy. Our work studies how insurance provision can reduce the precautionary savings motive and traces the macroeconomic implications. We take a partial equilibrium approach—that is, the risk-free rate in the economy is taken as given. In this sense, our approach is similar to the work of [Imrohoroglu \(1989\)](#), [Zeldes \(1989\)](#), [Deaton \(1991\)](#), and [Hubbard, Skinner and Zeldes \(1995\)](#), who also study how social insurance affects the precautionary savings motive.

We build on these works by taking into account the impact social insurance has on the endogenous debt pricing schedule. We also build on [Krueger and Perri \(2011\)](#). Their model features contingent contracts, resulting in no default occurring in equilibrium and credit supply *decreasing* when social insurance expands (financial autarky becomes less costly and thus default more tempting). Our model instead features non-contingent defaultable debt and leads to a positive credit supply response, which is consistent with our empirical estimates.

Additionally, our analysis of the impact of social insurance on credit markets complements concurrent work studying the "opposite" question: the impact of credit access on the design of optimal UI ([Braxton, Herkenhoff and Phillips, 2022](#)).

Third, we build on an empirical microeconomic literature studying the consumer finance consequences of expanding insurance. We present new evidence on revolving credit card debt and, using our model, quantify the welfare effects and decompose the underlying channels. Prior work on Medicaid finds that expansions reduced medical debt, missed debt and bill payments, reliance on payday loans, and debt in collections ([Allen et al., 2017](#); [Hu et al., 2018](#); [Miller et al., 2018](#); [Gallagher et al., 2019b](#); [Goldsmith-Pinkham et al., 2020](#)). Reduced debt and delinquency improved FICO scores after expansions, leading to lower interest rates on credit card offers ([Brevoort, Grodzicki and Hackmann, 2017](#)) and increased mortgage application approval rates ([C  lerier and Matray, 2017](#)). Our focus on borrowing complements [Gallagher, Gopalan and Grinstein-Weiss \(2019a\)](#), which finds that health insurance reduces savings among households experiencing financial hardship. Less saving does not immediately imply higher gross or net borrowing.<sup>9</sup> Using a synthetic DID, [Hu et al. \(2018\)](#) finds a statistically insignificant, small, and negative effect of Medicaid expansions on credit card balances. Our paper is the first, to our knowledge, to study the response of *revolving* credit card balances to Medicaid. Our empirical strategy also differs from [Hu et al. \(2018\)](#) in that we use ZIP rather than state-level variation in Medicaid eligibility, and we include the post-2014 expansions.

Research on unemployment insurance also finds evidence of improved financial resilience (lower mortgage default) and expanded credit access (lower interest rates and higher application approval rates) ([Hsu, Matsa and Melzer, 2018](#); [Matsa, Melzer and Zator, 2022](#)). Our paper also relates to [Aaronson, Agarwal and French \(2012\)](#), which documents strong and positive spending and collateralized debt increases among minimum wage workers following rises in the minimum wage. We build on their findings by documenting that revolving credit card debt also rises after the expansions of another part of the social safety net (Medicaid). We

---

<sup>9</sup>In contrast to standard models of consumption and saving, household borrowing presents a "credit card puzzle" in that households tend to hold both high-interest credit card debt and low-interest savings simultaneously ([Gross and Souleles \(2002\)](#)). This behavior is consistent with a motive to maintain a liquidity buffer in the presence of incomplete markets ([Telyukova, 2013](#); [Druedahl and J  rgensen, 2018](#)).

show that this rise is accompanied by a decline in default, improvements in credit scores, and increases in measures of credit supply (e.g., credit card approval rates).

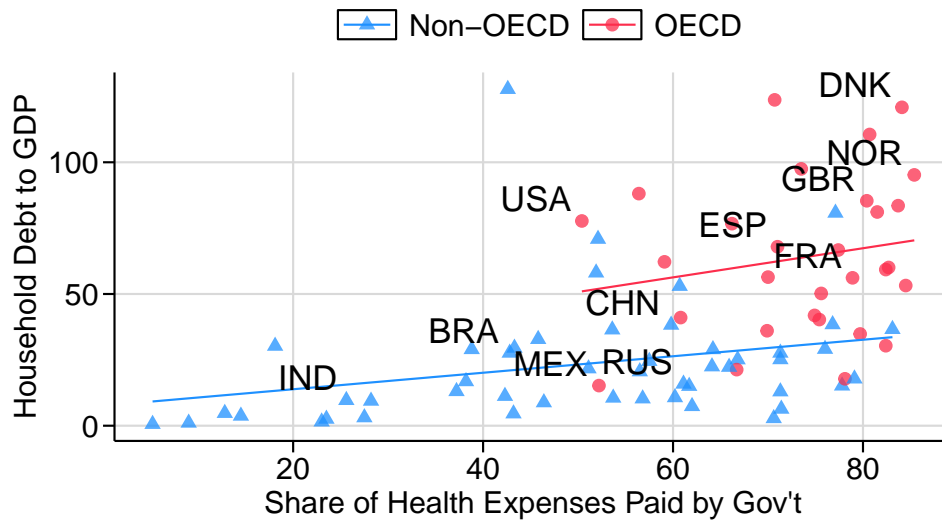

This paper is organized as follows. Section 2 presents background on the Medicaid expansions and the empirical analysis of the impact of expansions on credit card debt. Next, Section 3 presents the model. Section 4 analyzes policy counterfactuals on debt (its distribution and aggregate level) as well as welfare. We decompose the effect of expanding health insurance on borrowing into its direct impact on debt for households experiencing adverse shocks and its general equilibrium impacts through credit demand and supply. Section 5 concludes.

## **2 The Effect of Social Insurance on Household Debt: Evidence from Medicaid Expansions**

At the macro level, cross-country comparisons indicate the generosity of social insurance is *positively* related to household debt. Figure 2 plots the ratio of household debt to GDP versus the share of total health expenses paid by the government, a proxy for social insurance provision, across countries. Countries with more generous insurance have significantly higher levels of household debt. At the top right corner are the Scandinavian countries, which have both a high provision of social insurance and high levels of household debt. As viewed through the lens of our hypothesis, one reason Scandinavian households take on higher levels of debt is because they are more financially resilient—they are better insured against adverse events.

This section estimates the effect of expanded social insurance on household debt. We study one of the largest changes to the US social safety net in recent decades: the expansion of Medicaid under the Affordable Care Act (ACA). Our empirical strategy exploits both the staggered nature of the Medicaid expansions across states and within-state granular heterogeneity in the impact of the expansions. Examining a variety of credit outcomes, we find a positive relationship between credit card debt and Medicaid eligibility, as well as supporting evidence consistent with credit supply playing an important role in shaping the equilibrium response.

**Figure 2: Household Debt and Social Insurance across Countries**

Notes: Data come from the IMF Global Debt and WHO Global Health Observatory data repository.

## 2.1 Institutional Background: Medicaid

Medicaid is a program, administered jointly by state and federal governments, that offers low-income households free or low-cost health insurance. By the end of 2019, 64.3 million individuals—nearly 20% of the US population—were receiving health insurance through Medicaid. In the wake of COVID-19, the number of enrollees has steadily climbed to 85.3 million as of December 2022.<sup>10</sup> Medicaid spending is a large fraction of total US health care expenses, totaling \$597.4 billion in 2018 (or comprising 16% of aggregate health expenditures). To qualify for Medicaid, a household must have income below a specified threshold.<sup>11</sup>

The ACA expanded Medicaid in participating states by requiring these states to set the income eligibility threshold to at least 138% of the federal poverty level (FPL) for *all* adults. Participating states receive federal funds to support the costs of the Medicaid expansion. Prior to the ACA, only a handful of states offered Medicaid to adults aged 64 or under without dependents. After expanding, the uninsured population decreased 30% on average among participating states. The share of the population enrolled in Medicaid rose 4.37 percentage points

<sup>10</sup>We obtain enrollment count data from the Kaiser Family Foundation: <https://www.kff.org/other/state-indicator/medicaid-and-chip-monthly-enrollment>.

<sup>11</sup>Several states also use an asset-based means test in addition to the income threshold to determine eligibility. To expand Medicaid under the ACA, states were required to remove any asset-based means tests.

in expanding states. This average change in enrollment is within range of the estimated *causal* effect of the expansions on enrollments, which is 3-5 percentage points.<sup>12</sup> The crowding out of private and other sources of government insurance appears limited; the fraction receiving non-Medicaid sources of insurance fell 0.59 percentage points.<sup>13</sup> Figure 3 plots insurance type by income both before and after expanding.

**Figure 3: Health Insurance Type by Income (Pre- and Post-Expansion)**

*Notes:* The graphs plot the fraction of people with either Medicaid (left panel) or other non-Medicaid sources of insurance (right panel), such as private insurance or Medicare. We report averages both before (blue circles) and after (red triangles) states expanded Medicaid. We include non-expanding states in the "before" group. Insurance type is measured at the end of the year, while income is measured over the entire year. Note that some "high-income" households may qualify for Medicaid if, for example, they lost their job during the year and were eligible by the end of the year. This, and aggregation across household sizes, time, and states, is likely why the share with Medicaid is smooth with respect to income (as opposed to being discontinuous at eligibility thresholds). Source: American Community Survey (ACS), 2010 to 2020.

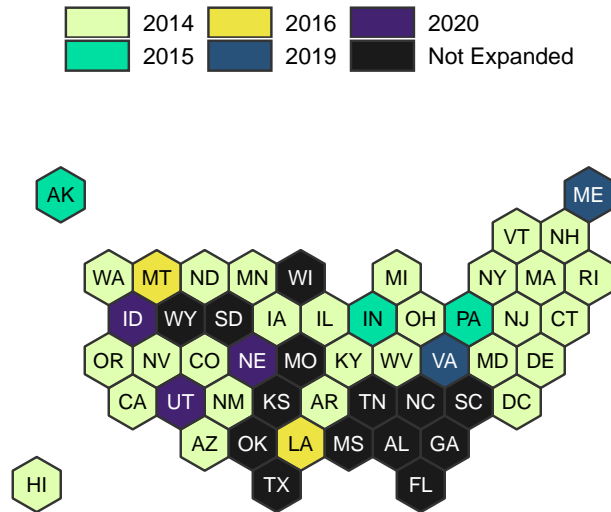

Participating in the expansion is optional, and the timing of adoption varied significantly across time (see Figure 4). The first, and most common, year of adoption was 2014. As of 2021, 36 states (and D.C.) have expanded Medicaid eligibility under the ACA.

The ACA was primarily financed by cuts to federal government spending on health care, taxes on insurers, and taxes on individuals. Congressional Budget Office (CBO) estimates projected the ACA to *reduce* budget deficits overall during the period 2013–2022 by \$109 billion (Congressional Budget Office, 2012). The ACA's projected costs to the federal government of expanding Medicaid, the Children's Health Insurance Program (CHIP), health insurance exchanges, and other non-coverage provisions totaled \$1,455 billion (approximately 0.6% of 2020's GDP per year). Health care-related government spending cuts were projected to save

<sup>12</sup>See, for example, Sommers et al. (2014); Frean et al. (2017); Kaestner et al. (2017); Courtemanche et al. (2019).

<sup>13</sup>These figures are calculated using American Community Survey (ACS) data from 2010 to 2020.

**Figure 4: Medicaid Expansion Dates**

*Notes:* Expansion dates come from the Kaiser Family Foundation.

\$741 billion over this same time period, accounting for 50.9% of the total cost. The primary source of these cuts were reductions in payment rates for hospital services rendered to Medicare and Medicare Advantage patients and reductions in Disproportionate Share Hospital (DSH) payments. DSH payments help compensate hospitals for the cost of uncompensated care (i.e., missing or partial payments owed by patients).

## 2.2 Data

This section describes the two main datasets used in our reduced-form analysis. The first is credit bureau data. The second dataset records Medicaid eligibility at the ZIP-code level. Throughout, we deflate nominal variables to real 2020 dollars.

**Experian Data.** Our credit bureau data comes from Experian and covers a random sample of 10 million US residents. This Experian sample is an annual panel spanning the period 2010 to 2021 and contains over 90 million borrower-level observations. A subset of outcomes are measured at a quarterly frequency over 2010–2020. Our sample is geographically representative in the sense that individuals are randomly sampled from ZIP codes in proportion to their ZIP code’s population share. In our empirical analysis, we aggregate the borrower-level data to the ZIP-code level. We drop ZIP codes with fewer than 150 borrowers reporting data and

ZIP codes that cannot be matched to our Medicaid eligibility data (these are mainly small ZIP codes). After these restrictions, we have 12,511 unique ZIP codes over 12 years.

**Experian Summary Statistics.** Table 1 presents summary statistics for our main credit outcomes of interest in the ZIP-code level sample. On average, 85% of borrowers in a ZIP have at least one credit card, and 22% obtained a new credit card in the past year. Average borrower-level credit card balances are \$4,299. We measure revolving (i.e., unpaid) balances as the difference between average monthly balances and average monthly payments. These monthly averages are available at a quarterly frequency in the Experian data. In our sample, borrowers carry \$3,680 on average in revolving balances each month. Within this sample, 60% of the borrowers have unpaid balances at least once per quarter; the rate is 71% among credit cardholders.

Our measure of unpaid balances may be subject to measurement error that depends on when balances are measured relative to the consumer's scheduled payment date.<sup>14</sup> Average use of revolving credit card debt in our sample is similar to estimates from regulatory data, suggesting that measurement error is close to mean zero.<sup>15</sup> Importantly, this measurement error will *unlikely* bias the regression analysis. Revolving balances will be a response variable in our regressions, and the timing of a consumer's billing cycle is likely unrelated to their state's Medicaid expansion.

We consider several additional variables that reflect credit access. In our sample, average credit card utilization is 31%, and average limits are \$18,013. Credit limits vary significantly across ZIP codes; the standard deviation is \$8,740. The average ratio of new accounts per credit card inquiry is 0.52, indicating that typically two inquiries are necessary to obtain one credit card. Credit card inquiries per year average 0.44 per borrower.

For default, we examine both measures of delinquency and whether borrowers have debt in collections. On average, 10% and 7% of borrowers have some debt that is 30 and 90 or

---

<sup>14</sup>Ideally, we would subtract payments from the *statement* balance at the end of the billing cycle. Average current balances will tend to understate statement balances when measured after the end of the billing cycle (and may overstate it when measured shortly before).

<sup>15</sup>Using regulatory data, Adams, Bord and Katcher (2022) report that around 68% of active credit card accounts are used to revolve in a given year and that approximately 75% of credit card balances are revolving at a given point in time. Alternatively, the share of revolvers is 52% in the 2019 Survey of Household Economics and Decisionmaking (SHED) and 45% in the 2019 Survey of Consumer Finances (SCF). However, Zinman (2009) argues that the SCF significantly under-reports credit card debt.

**Table 1: Summary Statistics for ZIP-Code Level Credit Outcomes**

	Mean	SD	25th %	50th %	75th %	N
1[Has CC] (%)	84.73	8.73	79.55	86.28	91.46	117,629

1[Any Col.]	23.61	11.81	14.5	21.89	30.92	117,629
Col. Bal.	664.6	436.73	351.17	566.75	872.22	117,629
Col. Bal./Income (%)	1.19	1.11	0.43	0.88	1.59	117,629
Vantage Score	683.92	36.95	659.03	684.65	710.26	117,629

*Notes:* This table reports ZIP-code level summary statistics for the main credit outcomes of interest from the Experian data. All variables are reported annually (June of each year) except for credit card balances (total and revolving) and the percentage of people that have revolving balances ("revolvers"). The latter are reported quarterly. We calculate revolving (i.e., unpaid) balances by subtracting credit card payments from total credit card balances. Nominal variables are CPI adjusted to be in terms of 2020 dollars. Throughout, "CC" denotes "credit card." The "Has CC" variable indicates the fraction of borrowers with at least one credit card, while the "New CC" variable captures people that obtained at least one new credit card in the past year. Balances, limits, and utilization are calculated across all credit cards. Utilization and limit calculations include households with zero credit cards. The "inquiries" variables reflect total activity in the past year. The delinquency variables reflect whether borrowers had any debt 30+ or 90+ days past due (excluding collections). The collections variables indicate the fraction of households with some debt in collections (non-medical and medical debt are tabulated separately). Our credit score measure is the Vantage Score.

more days past due (respectively). These measures of delinquency exclude debt in collections, which is even more common. On average, 24% of borrowers have at least some debt in collections.

Default is persistent. Among households that either become newly delinquent or have debt enter into collections, 38.9% are in default the following year. Of those, 5% are still in default four years later. Appendix Figure A.1 and Table A.8 report the default hazard rate for households in the Experian sample for a 10-year horizon.

**Medicaid Eligibility Data.** We combine several data sources to estimate Medicaid eligibility at the ZIP-code level. Adult household members are eligible for Medicaid if their income falls below a threshold, where the income threshold depends on household size and the number

of dependents. Directly calculating eligibility requires individual-level data containing ZIP codes, income, and household composition. Because such data are difficult to access, we instead estimate the eligible population share. Our estimation approach first estimates the income distribution for each ZIP-year using data from the IRS Statistics of Income (SOI). Next, relying on the law of iterated expectations and Bayes’ rule, we use the joint distribution of income and household size from the 2010 American Community Survey (ACS) to estimate the share of households with income below their corresponding Medicaid threshold. For details on our procedure, see Appendix B. We use IRS SOI data from 2009 to 2020 in our calculations. We obtain annual ZIP-code level data on Medicaid enrollment from the ACS.

**Eligibility Summary Statistics.** Table 2 reports summary statistics for our eligibility and income data.

**Table 2:** Summary Statistics for ZIP-Code Level Eligibility and Income Data

	Mean	SD	25th %	50th %	75th %	N
Elig. (%)	17.66	11.93	6.43	13.7	27.84	117,629
$\Delta$ Elig.	16.55	9.86	8.54	18.28	23.81	7,828
Avg. HH Inc.	79.86	63.18	51.22	63.1	85.5	117,629

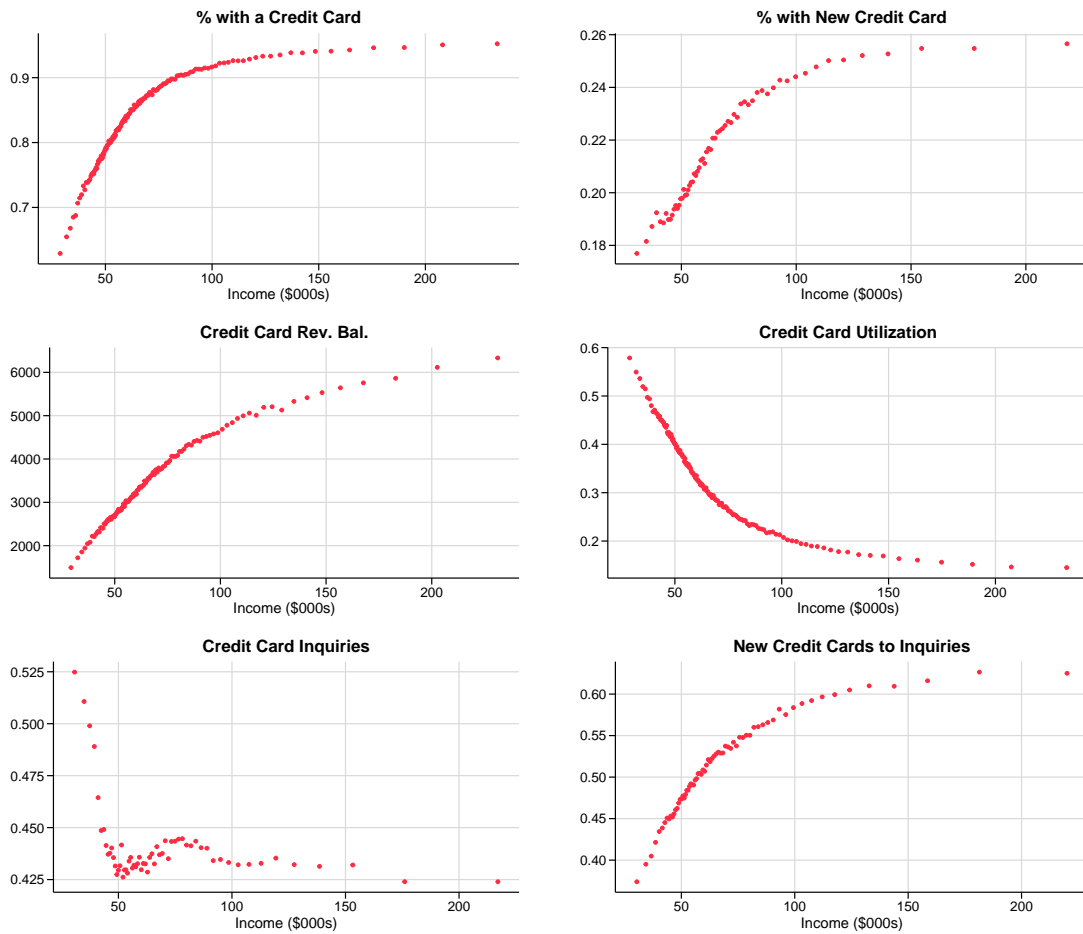

*Notes:* This table reports ZIP-code level summary statistics for the eligibility measures and income. Eligibility is calculated as described in the text, with additional details provided in Appendix B. The first row reports average eligibility across all ZIP codes and years. The second row reports the average change in eligibility in the first year of expansion (this excludes ZIP codes in states that did not expand). Average household income is the average adjusted gross income (AGI) reported in the ZIP code. Nominal variables are CPI-adjusted to be in terms of 2020 dollars.

### 2.3 Empirical Strategy: Continuous Difference-in-Difference

Identifying the causal effect of Medicaid eligibility is challenging. Eligibility depends on household income, which is likely correlated with omitted variables. Figure 5 shows that income is generally positively related to credit access and use. Comparing credit outcomes of eligible and non-eligible people would likely *understate* the causal effect of Medicaid eligibility, as such comparisons would conflate the causal effect with the direct effect of income and other factors correlated with income.

To overcome these identification challenges, we exploit quasi-experimental variation in the *size* of Medicaid expansions in a difference-in-difference (DID) analysis. We draw on

**Figure 5: ZIP-Code Level Credit Access and Income Facts**

*Notes:* This figure plots average income against credit outcomes, with all variables measured as the average within a ZIP code for a given year. All nominal variables deflated to 2020 dollars.

two sources of variation. First, we exploit cross-state variation arising from states' *pre-existing* Medicaid eligibility rules. Expanding under the ACA required states to raise the income eligibility limit to a common threshold of 138% of the federal poverty level for all adults aged 64 or less. States with previously stricter eligibility rules, such as lower income thresholds or rules precluding adults without dependents from eligibility, tended to experience larger changes in eligibility when expanding. Second, we exploit within-state variation due to differences in the *distribution* of income among low-income households. Specifically, ZIP codes where more households had income lie between the pre- and post-expansion income eligibility thresholds experienced a larger increase in eligibility.

Because we have a continuous measure of treatment intensity, we estimate a continuous DID. The DID compares ZIP codes with larger versus smaller shares of people that became newly eligible as a result of their state expanding Medicaid under the ACA. This approach is similar in spirit to that of [Goodman-Bacon \(2018, 2021b\)](#), which uses state-level variation in exposure to Medicaid expansions to estimate the impact on mortality. An advantage of using ZIP-code level variation is that we can include state-time fixed effects to account for the impact of state-level events coinciding with expansions. Motivated by similar concerns, [Dranove et al. \(2016\)](#) and [Garthwaite et al. \(2019\)](#) also use a continuous ZIP-code level DID to study the impact on health care utilization. We further refine their approaches by constructing an eligibility measure that takes into account how Medicaid eligibility cutoffs vary with family size.

We estimate

$$Y_{zct} = \beta (\text{Post}_{st} \times \text{NewElig}_{zs}) + \phi_z + \phi_{ct} + \gamma X_{zct} + \varepsilon_{zct}. \quad (1)$$

Above,  $Y_{zct}$  is an average credit outcome in ZIP code  $z$  (located in county  $c$  of state  $s$ ) in year  $t$ .<sup>16</sup>  $\text{Post}_{st}$  equals one if state  $s$  has expanded Medicaid as of year  $t$ . We capture the intensity of treatment with a continuous variable,  $\text{NewElig}_{zs}$ , which corresponds to the fraction of ZIP  $z$ 's population that became newly eligible for Medicaid over the first year of state  $s$ 's expansion (relative to the year before its expansion). ZIP code fixed effects,  $\phi_z$ , account

---

<sup>16</sup>Most of our outcome variables are measured annually, but a subset are observed at a quarterly frequency. The quarterly variables are credit card balances (both total and revolving).

for persistent differences across ZIP codes. We also include county-time fixed effects,  $\phi_{ct}$ , to account for the effects of other unobserved time-varying county and state-level shocks. We include time-varying controls ( $X_{zct}$ ), such as logged ZIP-code level income per household.<sup>17</sup> The coefficient of interest is  $\beta$  on the interaction term, which reflects the causal effect of an expansion that induced a 1 percentage point increase in eligibility. Throughout, we cluster our standard errors at the state level because the decision to expand Medicaid occurs at the state level.

When does OLS estimation of the above equation identify the causal effect  $\beta$ ? The key identifying assumption is that household credit outcomes would have evolved in parallel—across locations with high versus low changes in eligibility—if Medicaid had not expanded. Phrased differently, we assume that the size of the newly eligible population is uncorrelated with other factors *changing* at the time of the expansion. This assumption would fail if other policies were implemented along with the expansions that also targeted the newly eligible population.<sup>18</sup> Our design also mitigates this concern through the use of granular variation. The ZIP-level variation in the intensity of Medicaid expansions makes it possible to include country-time fixed effects. These fixed effects help account for the impact of other state or county-level policy changes on credit outcomes.

## 2.4 Empirical Results: The Effects of Medicaid Eligibility on Household Debt

**Credit Card Debt.** We first examine the response of credit card debt. Table 3 reports DID estimation results for these outcomes. We first document positive effects of increased eligibility on the extensive margin of credit card use. A 1 percentage point increase in a ZIP code’s Medicaid-eligible population leads to a 0.13 percentage point increase in the fraction of borrowers that have a credit card. The fraction of households that received a new credit card

---

<sup>17</sup>We verify that our results are robust to including richer controls for the income *distribution*, such as controlling for 19 percentiles of the distribution. Appendix Table A.1 reports these results for our main variable of interest: revolving credit card balances.

<sup>18</sup>In support of this assumption, we find evidence that credit card borrowing evolved similarly across both high- and low-income ZIP codes after expanding. This suggests it is unlikely that other policies altering low-income households’ credit use coincided with the Medicaid expansions. Our first test augments the regression above to include an interaction between an indicator for whether the ZIP code has above-median income and the post-expansion indicator. Our second test instead uses an interaction between  $\log(\text{AGI})$  and the post-expansion indicator. For credit card debt, we estimate a precise null effect for the income interaction terms in both the binary and continuous specifications (obtaining coefficients of -0.005 and 0.008, respectively) while still obtaining similarly large and statistically significant estimates for  $\beta$ .

in the last year grows by 0.22 percentage points in response to the same shock. Per newly eligible household, these correspond to a 13 and 22 percentage point increase (respectively).

In terms of total credit card balances, average ZIP-code level balances increase 0.96 percentage points in response to a 1 percentage point increase in eligibility. This corresponds to approximately a \$41.10 increase in average balances per capita. Examining *revolving* balances, we find that a 1 percentage point increase in eligibility increases credit card borrowing by 0.56 percentage points. The borrowing response constitutes a \$20.50 increase in average balances. Per newly eligible household, this corresponds to a \$2,050 increase in credit card borrowing, which is approximately 28% of total household credit card balances.<sup>19</sup> Additional heterogeneity analyses reveal that both the extensive and intensive margin responses are strongest in low-income ZIP codes.<sup>20</sup>

**Table 3: DID Results for Credit Card Debt**

	1[Has CC] (1)	1[New CC] (2)	log(CC Bal.) (3)	log(CC Rev. Bal.) (4)
NewElig <sub>zs</sub> × Post <sub>st</sub>	0.131*** (0.022)	0.217*** (0.015)	0.956*** (0.121)	0.557*** (0.116)
log(AGI <sub>zcst</sub> )	0.019*** (0.006)	-0.011*** (0.004)	0.082*** (0.022)	0.096*** (0.020)
Obs	117,628	117,628	372,222	372,222
R2	0.978	0.864	0.97	0.957
Mean	85%	22%	\$4,299	\$3,680

*Notes:* This table reports results from estimating the DID in Equation (1). Each specification uses county-time and ZIP code fixed effects and controls for logged ZIP-code level average adjusted gross income (AGI). Note that data are annual in columns 1-2 and quarterly in columns 3-4 (due to data availability). Standard errors are clustered by state. Nominal variables are CPI-adjusted to be in terms of 2020 dollars. The dependent variable is labeled above the column number, and its mean is reported in the bottom row. Statistical significance: 10%\*, 5%\*\* , and 1%\*\*\*.

While large, the estimated borrowing response is plausible. First, this large response is consistent with households going from little to no credit card usage to newly having access to a credit card, and beginning to catch up to more typical levels of credit card balances.

Second, the DID estimates the credit card response for up to 12 years before and after

<sup>19</sup>The 28% figure comes from dividing \$2,050 by \$7,210, where the \$7,210 is average household-level credit card balances as of 2019. We calculate this figure using the aggregate credit card balance data from the Federal Reserve Bank of New York’s Consumer Credit panel and household population count data from the American Community Survey.

<sup>20</sup>See Appendix Table A.5.

expanding. For each household made newly eligible *at the time* of expansion (our explanatory variable), more households likely end up eligible in the *following years* as a result of adverse events such as job loss. Putting our estimates in terms of *newly* eligible households likely overstates the impact in terms of the number of households that access Medicaid at some point *over* the next 12 years.

Third, credit demand and supply may also change for borrowers that never become eligible during the period of study. For example, households at risk of adverse events may expect that they are more likely to qualify for Medicaid if an adverse event occurs. Even if these particular households do not experience an adverse event, credit supply may respond positively to non-eligible households if underwriting models suggest that they present a lower risk of default after the expansion. In our structural analysis, our model allows these effects to be present.

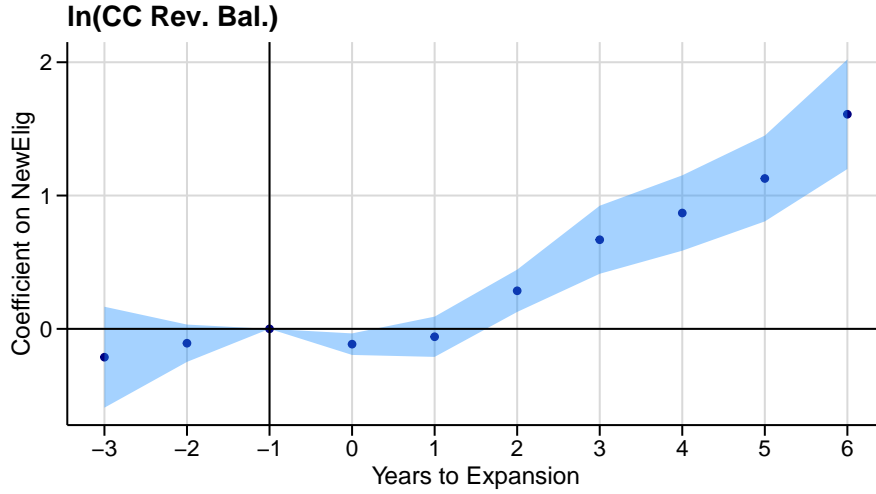

Fourth, our large estimates are consistent with other empirical evidence on spending responses to social insurance. Notably, [Aaronson et al. \(2012\)](#) estimate strong spending responses to minimum wage hikes. They find that a \$1 rise in the minimum wage increases quarterly income and spending by \$250 and \$800 (respectively) among households receiving over 20% of their income from minimum wage labor.

**Pre-trend Testing and Dynamic Estimates.** We estimate a dynamic version of Equation (1), where we replace the post-treatment indicator with a set of categorical variables reflecting years relative to expansion. Figure 6 plots these estimates. Prior to expanding, we see no evidence of pre-trends. That is, the subsequent change in the share of the population that becomes newly eligible does not predict differential trends in credit card debt prior to expansion. After expanding, revolving balances gradually increase over time.

**Credit Demand and Supply Proxies.** Next, to shed further light on the role of supply and demand, we examine proxies for these two forces in Table 4. Our proxy for credit card demand is the number of credit card inquiries per borrower in the past year.

We estimate that a 1 percentage point increase in a ZIP code's eligible population increases inquiries by 0.0055 per borrower (approximately 1 new inquiry per 180 individuals).

**Figure 6:** Dynamic Estimates for Revolving Balances.

*Notes:* This figure plots dynamic DID estimates at multiple horizons before and after Medicaid expansions. The shaded area is a 95% confidence interval for standard errors clustered at the state-level.

**Table 4:** DID Results for Credit Card Demand and Supply Proxies

	Demand	Supply		
	CC Inq. (#) (1)	log(CC Lim.) (2)	CC Util. (%) (3)	New CC to Inq. (4)
$\text{NewElig}_{zst} \times \text{Post}_{st}$	0.553*** (0.041)	0.364*** (0.119)	-0.358*** (0.033)	0.039 (0.036)
$\log(\text{AGI}_{zst})$	-0.072*** (0.010)	0.287*** (0.028)	-0.019** (0.009)	0.036*** (0.004)
Obs	117,628	117,628	117,628	117,628
R2	0.939	0.986	0.980	0.848
Mean	0.44	\$18,013	31%	0.52

*Notes:* This table reports results from estimating the DID in Equation (1). Each specification uses county-year and ZIP code fixed effects and controls for logged ZIP-code level average adjusted gross income (AGI). Standard errors are clustered by state. Nominal variables are CPI-adjusted to be in terms of 2020 dollars. The dependent variable is labeled above the column number, and its mean is reported in the bottom row. Statistical significance: 10%\*, 5%\*\* and 1%\*\*\*.

This suggests that demand may be contributing to the equilibrium rise in credit card debt.

For our supply proxies, we consider credit limits, the ratio of credit card balances to credit limits (utilization), and the ratio of new credit cards to credit card inquiries (over the past year). Overall, we find evidence consistent with a positive credit supply response to expansion. A 1 percentage point increase in a ZIP code’s eligibility leads to a 0.36 percentage point

increase in credit limits, corresponding to a \$65.75 increase. In dollar terms, this is larger than the implied change in either total or revolving balances. Indeed, utilization decreases 0.35 percentage points per 1 percentage point increase in the eligible population. Thus, despite the increase in credit card borrowing, credit constraints are overall relaxed in the sense of credit limits becoming less binding.

Lastly, we estimate a precise null effect (0.039) for the impact of Medicaid eligibility on the ratio of new credit cards to inquiries. This finding is also consistent with an expansion of credit supply. To see this, first note that this flat response of the credit card application success rate happens *despite* coinciding with a rise in the number of inquiries. Additionally, if marginal applicants are less likely to be successful than the average applicant, the flat response of the average success rates would indicate increased success rates for marginal applicants (relative to what they would experienced absent expanding Medicaid).

These proxies have several limitations. First, we note that inquiries are an equilibrium outcome that may be influenced by marketing practices of credit card lenders and households' perceptions of lending standards, making them an imperfect proxy for demand. Second, we would ideally also observe the response of credit card interest rates to gauge the plausibility that the rise in credit card debt is supply driven. While interest rates are not available in our sample, other work using credit card offer data finds evidence of reduced credit card APRs. [Brevoort et al. \(2017\)](#) estimate that Medicaid expansions led to improvements in credit card offer terms worth \$520 million per year. Ultimately, we rely on our model to quantify the roles of supply and demand.

**Financial Resilience.** Finally, we turn to measures of default and find evidence indicating that increased eligibility improved households' financial resilience in Table 5. We first examine the likelihood a household is 30- or 90-day delinquent on debt, finding a small and statistically insignificant effects of Medicaid eligibility. This indicates that household "debt tolerance" has increased in the sense that, despite households increasing credit card debt overall, they do not become more likely to enter delinquency.

Next, we study more severe forms of default and find that Medicaid eligibility reduces debt in collections. A 1 percentage point increase in eligibility reduces the likelihood of having

debt in collections by 0.11 percentage points. Similarly, the amount of debt in collections relative to average income (AGI) also shrinks by 0.04 percentage points in response to a 1 percentage point rise in eligibility. In relative terms, this constitutes a 3.25% reduction in this ratio. Note also that some households, who would have otherwise have had debt enter collections, may not entirely avoid default and instead experience milder forms of default such as delinquency. Overall, households appear to become more financially resilient as a result of increased Medicaid eligibility.

**Table 5: DID Results for Default and Credit Scores**

	1[Delinquency]		Debt in Collections		Credit Score
	30+ Days (1)	90+ Days (2)	1[Any Col.] (3)	Col./Inc. (4)	Vantage Score (5)
$\text{NewElig}_{zs} \times \text{Post}_{st}$	0.022 (0.013)	-0.004 (0.011)	-0.103*** (0.026)	-0.039*** (0.011)	0.143 (0.115)
$\log(\text{AGI}_{zcsst})$	-0.014*** (0.003)	-0.010*** (0.003)	-0.060*** (0.006)	-0.008*** (0.002)	0.192*** (0.024)
Obs	117,628	117,628	117,628	117,628	117,628
R2	0.914	0.901	0.982	0.940	.987
Mean	10%	7.2%	24%	1.2%	684

*Notes:* This table reports results from estimating the DID in Equation (1). Note that the delinquency measure here is not restricted to delinquency on credit cards. It will also reflect delinquency on mortgages, student loans, and so on. Each specification uses county-year and ZIP code fixed effects and controls for logged ZIP-code level average adjusted gross income (AGI). Standard errors are clustered by state. Nominal variables are CPI-adjusted to be in terms of 2020 dollars. The dependent variable is labeled above the column number, and its mean is reported in the bottom row. Statistical significance: 10%\*, 5%\*\*, and 1%\*\*\*.

The improved financial resilience of borrowers may also translate into higher credit scores. We estimate an economically significant (but statistically insignificant) increase in credit scores in response to expanded Medicaid. Our point estimate implies that a 1 percentage point increase in eligibility leads to a 0.14 increase in consumers' average Vantage Score. This effect is close in size to the 0.19 increase that is predicted by a 1% rise in average income. We note also that we find statistically significant increases in credit scores when we separately estimate our regressions in ZIP codes with above or below median income (see Appendix Table A.7).

To sum up, we find that expanding Medicaid eligibility increased both the prevalence of credit cards and revolving credit card balances. We find evidence suggesting both supply

and demand contributed to the increase in equilibrium credit card usage. Lastly, we find that households appear more financially resilient in terms of reduced default, which could drive an increase in credit supply in response to expanded Medicaid eligibility.

**Treatment Effect Heterogeneity Robustness.** Recent econometric work highlights that when the timing of treatment is staggered and treatment effects are heterogeneous, standard DID estimators can identify a weighted average treatment effect (e.g., [Goodman-Bacon, 2021a](#)). These weights can sometimes be *negative*, biasing estimates in the opposite direction of the true (unweighted) average treatment effect. Settings like those in this paper, in which there are many *early* treated units, are vulnerable in theory to having negative weights ([Roth, Sant'Anna, Bilinski and Poe, 2022](#)). This suggests that the estimates above may tend to understate the true treatment effects.

To address this concern, we verify that our results are robust to using a "stacked" DID estimator (as in [Cengiz, Dube, Lindner and Zipperer, 2019](#)). The idea of this approach is to restructure the data and regression in order to estimate the treatment effect using only "good comparisons." The problematic negative weights that may arise for the standard two-way fixed effect (TWFE) estimator are due to its use of "bad comparisons". The "bad comparisons" occur when newly-treated units are compared to previously-treated units.<sup>21</sup> The stacked approach instead relies only on "good comparisons" (or "clean controls") of never-treated units to treated units.<sup>22</sup>

We implement the stacked DID as follows. We first split our sample into several groups based on their expansion year (2014, 2015, 2016, 2019, or 2020). For each group of expanders, we append rows for the non-expanders. We create a group-identifier for each group and then "stack" observations for each group into a single data table. We then estimate a modified DID

---

<sup>21</sup>The problem with such comparisons is that already-treated units do not generally provide a valid counterfactual for newly-treated units. For example, if treatment effects grow over time, the change in outcomes for already-treated units reflected both their potential outcomes (absent treatment) and any subsequent changes in treatment effects. Therefore, in this scenario, subtracting the change in outcomes for already-treated units from the change for newly-treated units would tend to understate the true treatment effect.

<sup>22</sup>For a helpful, more detailed discussion of the "stacked" approach, see [Baker, Larcker and Wang \(2022\)](#).

regression, specified below:

$$Y_{zcstg} = \beta (\text{Post}_{stg} \times \text{NewElig}_{gzs}) + \phi_{zg} + \phi_{ctg} + \gamma X_{zcst} + \varepsilon_{zcst}.$$

The regression above modifies our baseline, Equation (1), by allowing the ZIP and county-time fixed effects ( $\phi_{zg}$  and  $\phi_{ctg}$ , respectively) to vary by group  $g$ . Estimating the modified equation results in effectively estimating the treatment effect for each group separately and then taking an average of these estimated treatment effects.

Overall, we find that the stacked specifications yield quantitatively similar estimates. Appendix Tables A.2, A.3, A.4 report estimation results. Generally, the stacked regressions yield estimates within two to three decimal points of those obtained via TWFE estimation on the same sub-sample and with similar statistical significance. We create "balanced panels" by restricting the stacked sub-samples to include the same number of pre- and post-expansion years. Since only one and two years of post expansion data are available for the 2019 and 2020 expansions (respectively), in this robustness analysis we use only data for 2014, 2015, and 2016 expanders (constituting 94% of our original sample). Since including later expansions comes at the cost of including fewer years of data, and treatment effect appear to grow over time (Figure 6), we present three sets of results that vary in whether they include the 2015 and 2016 expanders. To quantify gauge the possible biased induced by "bad comparisons," the tables also display TWFE estimates for the same sub-samples.

Notably, our stacked DID estimate for revolving balances is 0.602 for the set of 2014 expanders, which is close to its TWFE counterpart obtained on the same sub-sample (0.598).<sup>23</sup> This suggests that bias related to treatment effect heterogeneity is small in our setting. Our estimates become smaller (but remain positive and highly statistically significant) when adding additional expanders and shortening the horizon over which we estimate. This is because the shorter horizon excludes the later years, where the estimated treatment effects are largest.

---

<sup>23</sup>Note that the 0.598 estimate differs from the 0.557 estimate in Table 3 because it is estimated the subset of never-expanders and 2014 expanders. One reason these estimates are similar is that 85% of our full sample comes from never-expanders and 2014-expanders.

### 3 Model

In this section, we develop an incomplete-markets heterogeneous-agents model with health expenditure shocks, credit delinquency, and health insurance. Households face idiosyncratic income shocks as well as idiosyncratic health expenditure shocks. They can save and borrow using a one-period non-state-contingent asset and can choose not to repay their debt obligations. After renegeing on their debt obligations, their debt enters a delinquent state, and the household is excluded from financial markets and suffers a utility loss. In every period, delinquent debt can stochastically get a haircut (i.e., be reduced by some percentage). Households can exit the delinquency state by repaying their debt.

Credit to households is supplied by credit card companies. These companies have access to funds at the risk-free interest rate, which we assume to be exogenous. The assumption that the risk-free rate is constant, rather than the aggregate net supply of debt, allows us to study how different policies affect the aggregate stock of household debt in the economy. We assume that credit card companies are risk neutral and behave competitively. As a result, the interest rate spread a household pays on its loans is such that lenders' expected profits equal zero.

We use the model to study the effects of different insurance policies on the aggregate stock of debt, wealth inequality, and welfare.

#### 3.1 Household problem

There is a continuum of measure one of households in the economy, denoted by  $i \in (0,1)$ . Household's  $i$  income at time  $t$  is denoted by  $y_{it}$  and evolves according to a compound Poisson process:

$$\ln y_{it} = \begin{cases} \rho \ln y_{it-1} + \epsilon_{it}^y & \text{w.p. } \lambda_y, \\ \ln y_{it-1} & \text{w.p. } 1 - \lambda_y, \end{cases} \quad (2)$$

where  $\lambda_y$  is the probability that an income shock arrives in a period. If such shock does not arrive, the household's income does not change. Given an income shock, the household income follows an AR(1) process, where  $\rho$  is the degree of persistence and  $\epsilon_{it}^y$  is an idiosyncratic

income shock with mean zero and variance  $\sigma_{\epsilon,y}^2$ .<sup>24</sup>

In addition to income risk, households are subject to stochastic medical expenditure shocks, denoted by  $m_{it}$ . The stochastic expenditure shocks follow a log-normal distribution with mean  $\mu_e$  and variance  $\sigma_e^2$ .

Medical bills are partially covered by health insurance. We allow the type of insurance to vary exogenously with household income. Health insurance covers a share of the medical bill due. We denote the share of medical bills a household has to pay out-of-pocket as  $o(y_{it})$ . Note that the out-of-pocket share depends only on the current household income, as we assume insurance varies only with household income.

Each household has access to non-state-contingent one-period debt, denoted by  $b_{it}$ . A negative value of  $b_{it}$  represents household savings. In the beginning of each period, the household can choose to repay or renege on its debt obligations. The household's decision to repay debt depends on its total debt, its level of income, and the size of its current medical bill. Households face an interest rate schedule for the amount of borrowing they choose, which we denote by  $r(b', y)$ .<sup>25</sup> The price of debt is denoted by  $q(b', y) = \frac{1}{1+r(b', y)}$ . We denote the total amount of repayments owed by the household by  $\tilde{b}_{it} = b_{it} + o(y_{it})m_{it}$ . Note that  $\tilde{b}$  is the relevant state variable from the perspective of the household.

The household's present discounted value is denoted by  $V(\tilde{b}, y)$ , where  $\{\tilde{b}, y\}$  are its individual state variables. This value function is given by the max between the present discounted value of repaying debt obligations, denoted by  $V^r(\tilde{b}, y)$ , and the value of renegeing and declaring delinquency, denoted by  $V^d(\tilde{b}, y)$ :

$$V(\tilde{b}, y) = \max \left\{ V^r(\tilde{b}, y), V^d(\tilde{b}, y) \right\}. \quad (3)$$

Conditional on the decision to repay its debt obligations, the recursive problem of the

---

<sup>24</sup>The assumption that income shocks occur with probability  $\lambda_y$  allows us to match the high kurtosis of income changes observed in the data. The high kurtosis is quantitatively important for matching delinquency rates in the data.

<sup>25</sup>The size of medical bill does not appear in the interest rate schedule as it is independent across periods.

household with total debt obligations  $\tilde{b}$  and income  $y$  is given by

$$\begin{aligned} V^r(\tilde{b}, y) &= \max_{c, b'} u(c) + \beta \mathbb{E}V(b' + o(y')m', y'), \\ \text{s.t.} \quad c + \tilde{b} &\leq y + q(b', y)b', \end{aligned} \quad (4)$$

where  $u(\cdot)$  is the utility of the household from consumption, which is assumed to be strictly increasing, concave, and continuously differentiable. The household's discount factor is  $\beta$ .

When a household reneges on its debt obligations, the debt moves into a delinquency state. A household with debt in a delinquency state cannot save or borrow and suffers a utility cost  $\xi$ . At the end of the period, the household receives a stochastic haircut on its debt obligations. The haircut, denoted by  $\delta$ , is assumed to follow a Power distribution with shape parameter  $\alpha$ . That is, the probability that the share of debt forgiven is less than  $\delta$  is given by  $\delta^\alpha$ .

The value of the household in the delinquent state is given by

$$V^d(\tilde{b}, y) = u(y) - \xi + \beta \mathbb{E}V((1 - \delta)\tilde{b} + o'(y')m', y'). \quad (5)$$

The timeline in every period is as follows. First, the household learns its current income and medical bill. Then, it decides whether or not to repay its outstanding debt obligations. If it decides to repay its debt obligations, it chooses the level of consumption and borrowing. If it decides to renege on its debt obligations, it consumes its income, suffers a utility loss, and at the end of the period draws a stochastic haircut rate.

We denote the delinquency policy function of a household with total debt obligations  $\tilde{b}$  by

$$d(\tilde{b}, y) = \mathbf{1} \left[ V^r(\tilde{b}, y) < V^d(\tilde{b}, y) \right], \quad (6)$$

where  $\mathbf{1}$  is the indicator function. The function  $d(\tilde{b}, y)$  equals 1 when the household defaults. When indifferent, we assume the household repays its debt obligations.

### 3.2 Credit supply

Credit to households is supplied by risk-neutral credit card companies. Perfect competition among these companies ensures an expected zero-profit condition holds in equilibrium. We assume credit card companies have unlimited access to funds at the risk-free interest rate, which we denote by  $r^f$ .

Debt in the economy is a hybrid of short-term and long-term debt. Debt is of short maturity in nature, as households need to repay their debt obligations in the following period.<sup>26</sup> However, when debt becomes delinquent, credit card companies do not receive payments within that period. Instead, they need to wait until the household decides to repay its debt—either because it received a sufficiently large haircut or because its income level changes so that it decides to repay.

The zero-profit condition that pins down the price of debt,  $q(b', y)$ , is

$$q(b', y)(1 + r_f) = [1 - \mathbb{E}(d(b' + o(y')m', y'))] + \mathbb{E}[d(b' + o(y')m', y')(1 - \delta')q((1 - \delta')(b' + o(y')m'), y')]. \quad (7)$$

That is, the credit companies equate the cost of their loan (LHS) with its return (RHS). The return from the loan is the sum of two parts. If the debt is repaid, the credit company receives its full face value. If the debt is delinquent, which happens with probability  $\mathbb{E}(d(b' + o(y')m', y'))$ , the creditor is left with a claim on a delinquent debt. The worth of such claim is given by  $(1 - \delta')q((1 - \delta')(b' + o(y')m'), y')$ . The fixed point function  $q(\cdot)$  that solves equation (7) is the debt pricing schedule. As the following proposition shows, this function exists and is unique.<sup>27</sup>

**Proposition 1.** *Given a default policy function,  $d(\tilde{b}, y)$ , there exists a unique pricing schedule  $q(b', y)$  that satisfies equation (7).*

---

<sup>26</sup>Note that households can potentially roll over their debt by borrowing to cover their current debt obligations.

<sup>27</sup>The proof is in Appendix C.

### 3.3 Stationary Equilibrium

We denote the joint distribution of households across total debt obligations and income levels at the beginning of the period, after the expenditure shock realization, by  $\Lambda(\tilde{b}, y)$ . Four components characterize the law of motion for this joint distribution: (i) the borrowing decision of households,  $b'(\tilde{b}, y)$ , (ii) the debt pricing schedule,  $q(b', y)$ , (iii) the household's default decision,  $d(\tilde{b}, y)$ , and (iv) the exogenous processes of income, expenditure shocks, and haircuts. The law of motion for the joint distribution is defined as follows. For all Borel sets  $\mathcal{B} \times \mathcal{Y} \subset \mathbb{R} \times \mathbb{R}^+$ ,

$$\begin{aligned} \Lambda'(\mathcal{B} \times \mathcal{Y}) &= \int_{m'} \int_{y' \in \mathcal{Y}} \int_{\mathcal{B}(\tilde{b}, y, m')} d\Lambda(\tilde{b}, y) dF(y'|y) dG(m') \\ &\quad + \int_{\delta} \int_{m'} \int_{y' \in \mathcal{Y}} \int_{y, ((1-\delta)\tilde{b} + o(y')m') \in \mathcal{B}} \mathbb{1}[d(\tilde{b}, y)] d\Lambda(\tilde{b}, y) dF(y'|y) dG(m') dH(\delta), \end{aligned} \quad (8)$$

and

$$\mathcal{B}(\tilde{b}, y, m') = \{(\tilde{b}, y) \text{ s.t. } d(\tilde{b}, y) = 0 \text{ and } b'(\tilde{b}, y) + o(y')m' \in \mathcal{B}\},$$

where  $F(\cdot)$ ,  $G(\cdot)$ , and  $H(\cdot)$ , are the CDF of the different exogenous variables. In the stationary equilibrium, the distribution  $\Lambda(\tilde{b}, y)$  is constant over time. The definition of the stationary Markov-perfect equilibrium is as follows.

**Definition 1** (Equilibrium). *A stationary Markov-perfect equilibrium is given by a default policy function  $d(\tilde{b}, y)$ , a borrowing policy function  $b'(\tilde{b}, y)$ , a debt pricing schedule  $q(b', y)$ , and a joint distribution of households across total debt and income levels,  $\Lambda(\tilde{b}, y)$ , such that*

1. *The default and borrowing policy functions solve the household's problem given the debt pricing schedule.*
2. *The debt pricing schedule satisfies the zero-profit condition, (7).*
3. *The joint distribution of households across debt and income levels is stationary.*

### 3.4 Calibration

We calibrate the risk-free interest rate in the economy to 2% and assume that households have log utility in consumption,  $u(c) = \ln(c)$ . We can divide our calibration into five sets of struc-

tural parameters. First, there are two preference parameters—the discount factor  $\beta$  and the disutility of delinquency  $\zeta$ . Second, there is the haircut process parameter—the shape parameter of the Power distribution,  $\alpha$ . Third, there are three parameters governing the income process—the arrival rate of income shocks  $\lambda_y$ , the persistence of income  $\rho$ , and the variance of income shocks  $\sigma_{\epsilon,y}^2$ . Fourth, there are two parameters governing the health expenditure process—its log mean  $\mu_e$  and variance  $\sigma_e^2$ . Finally, we need to calibrate the out-of-pocket share function  $o(y)$ .

We proceed as follows. We use income data from the Panel Study of Income Dynamics (PSID) to calibrate the income process. We use the Medical Expenditure Panel Survey (MEPS) to calibrate the parameters governing health expenditure shocks and the out-of-pocket function. We then calibrate the preference parameters and haircut shape parameter to match several features of credit card debt in the data.

**Income Process Parameters.** We calibrate the income process parameters to match key moments of household income dynamics from the PSID. Our sample includes households whose head is between the ages of 25–55. The sample period is 1999–2019. The three moments we target are the two-year autocorrelation of log household income (0.837), the standard deviation of two-year log-income changes (0.536), and the kurtosis of two-year log-income changes (5.586).<sup>28</sup> The calibration yields an arrival rate of income shocks  $\lambda_y = 0.348$ , so that income shocks arrive on average every 2.8 years. The calibrated persistence of income conditional on an income shock is  $\rho = 0.756$ , and the variance of income shocks is  $\sigma_{\epsilon,y}^2 = 0.378$ .<sup>29</sup>

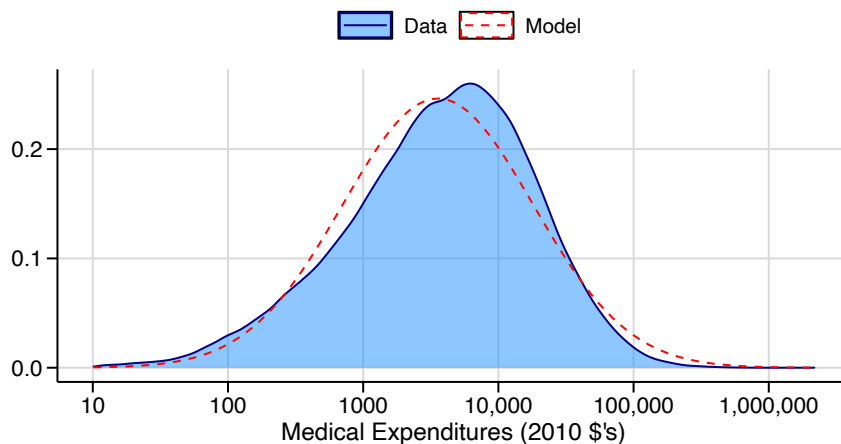

**Health Expenditure and Insurance Parameters.** We calibrate the mean log expenditure and its variance to match the distribution of annual medical expenditures of households in the MEPS data over 2000 to 2017. We find a mean expenditure of 8% of median income and a variance of 2.62. Figure 7 compares the calibrated distribution to its empirical counterpart. The calibrated parameters imply that a medical expenditure one standard deviation above the average equals 40% of median income. Recall that the expenditure shocks, in both the

<sup>28</sup>The data moments are in line with the income moments in [Güvenen et al. \(2015\)](#), who use Social Security Administration data on the annual income of males in the US.

<sup>29</sup>In Appendix C, we show how the moments map to these three parameters.

data and the model, are not the amounts that households have to pay out-of-pocket.

**Figure 7:** Distribution of annual medical expenditure

*Notes:* Data source: Medical Expenditure Panel Survey (MEPS).

The MEPS dataset also contains information on household income, insurance type, and out-of-pocket (OOP) expenditures. To construct the out-of-pocket share as a function of income, we proceed in two steps. First, we split insurance types into three categories: Medicaid, non-Medicaid insurance, and uninsured. Non-Medicaid insurance includes households with private insurance (including employer sponsored) and Medicare. We compute the average OOP share for each insurance type. The average OOP share in Medicaid is 6.8%, 27.5% under non-Medicaid insurance, and 63% for the uninsured.

Second, using a log-linear function, we approximate the share of households with each insurance type. We compute these approximations both before and after the expansion of Medicaid. Figure 3 displays the empirical shares alongside our approximation. The stationary distribution of our benchmark model uses the pre-expansion approximations, while the post-expansion counterfactual economy uses the post-expansion approximations.

We combine the relationship between insurance type and income along with the OOP share by insurance type to impute the average OOP share by income. Specifically, the OOP share in our model is

$$oop(y) = \Pr(\text{Medicaid}|y) \times 6.8\% + \Pr(\text{Other}|y) \times 27.5\% + \Pr(\text{Uninsured}|y) \times 62.7\%. \quad (9)$$

A key advantage of this two-step approach, relative to directly estimating the OOP share along the income distribution, is that we can conduct counterfactuals in which we change the share of households under each insurance type.

**Preference and Haircut Parameters.** There are three remaining parameters: (i) the discount factor  $\beta$ , (ii) the disutility of delinquency  $\zeta$ , and (iii) the haircut distribution shape parameter  $\alpha$ . We use an indirect inference procedure to calibrate these parameters.

We target four credit card moments in the pre-expansion period. These moments include the aggregate level of revolving credit card debt in the data, the share of revolving credit card debt owed by the bottom 40% of households, the delinquency share across households, and the hazard rate of delinquency.<sup>30</sup>

Note that not all debt in our model corresponds to credit card debt in the data. Consider, for example, a low-income households who can only borrow at very high interest rate spreads, and as a result decides to have no debt. Suppose such households suffers a large medical shock, which it chooses not to repay. As a result, such household has delinquent debt. We do not consider this form of debt to be credit-card debt, as no lender extended any loans to this household. In particular, credit card in the model corresponds to any non-delinquent debt households owe, as well as delinquent debt that was given to the household in the previous period by a credit card company.

In addition to the four credit card moments, we also target the main regression coefficient from our empirical analysis: a 1 percentage point increase in a ZIP code’s Medicaid-eligible population increases credit card borrowing by 0.56%. To construct a model-implied regression coefficient, we proceed as follows. Starting from the pre-expansion ergodic distribution, we divide households into ZIP codes according to their income.<sup>31</sup> We then study the transition dynamics following the expansion of Medicaid. We discuss this counterfactual experiment in detail in Section 4. We construct the estimand in the model in three steps. First, for each ZIP code, we construct the share of newly Medicaid-eligible households based on the

---

<sup>30</sup>The revolving credit card data at the household level are obtained from the PSID, while the delinquency rate as well as the hazard rate of delinquency are obtained from the Experian dataset. The data counterpart of delinquency is an individual with 90–180 days of delinquent credit card debt or any debt in collection.

<sup>31</sup>To do so, we use IRS SOI data to obtain the income distribution in every ZIP code in the US. We then draw households from the ergodic distribution so that we exactly match the observed income distribution within each ZIP code and across ZIP codes.

income distribution in that ZIP code as well as the difference between the estimated pre- and post-expansion Medicaid insurance across household income.<sup>32</sup> Second, for each ZIP code, we analyze the impact the expansion has on credit card debt for the first five years following the expansion. We do so by comparing the log amount of credit card debt in the ZIP code following the expansion of Medicaid, relative to what would be the log amount of credit card debt absent the implementation of the expansion.<sup>33</sup> Finally, we compute the average treatment effect across ZIP codes.

The estimation targets as well as the model fit are reported in Table 6. All model parameters are reported in Table 7. The model does a reasonable job at matching the data targets, considering we are using 3 parameters to match 5 targets. The estimated annual discount factor  $\beta$  is estimated to be 0.86. This relatively low discount factor is needed for households to borrow despite the non-negligible interest rate spreads.<sup>34</sup>

**Table 6: Estimation Targets and Model Fit**

	Data	Model
Aggregate credit card debt (% of median income)	5.3%	6.8%
Credit card debt share held by bottom two quintiles	19.3%	21.8%
Delinquency share	27.0%	20.6%
Delinquency hazard rate	38.9%	43.5%
Eligibility effect on credit card debt	0.56	0.38

*Notes:* This table presents the targeted data moments as well as the model-implied moments of the estimated model. The last row reports the main regression coefficient from Section 2 and the estimand in the model.

The estimated value for the disutility of delinquency is  $\zeta = 0.246$ . This value implies that households are indifferent between the periodic non-pecuniary cost of delinquency and a 22% drop in consumption. The sizeable delinquency cost is what allows households to maintain

<sup>32</sup>Since our model only uses data on the insurance type individuals have, we need to take a stand on the take-up rate in order to obtain Medicaid eligibility. For the analysis, we use a take-up rate of 50%.

<sup>33</sup>Note that while the national ergodic distribution of income does not vary over time in the steady state, the income distribution within each ZIP code does slowly converge toward the national stationary distribution. For that reason, we do not compare the log amount of debt post-expansion to the same variable before the expansion, but rather to the log amount of debt along the transition dynamics in each ZIP code absent the expansion of Medicaid.

<sup>34</sup>The estimated value of the discount factor is within the range of impatient and patient households found in Chatterjee et al. (2020) and Aguiar et al. (2020). Chatterjee et al. (2020) construct a quantitative model of credit scores and estimate the discount factor of impatient households to be 0.81 and that of patient households to be 0.93. Aguiar et al. (2020) use the PSID to study the behavior of hand-to-mouth households and estimate preference heterogeneity across households. They estimate that the discount factor for impatient households is 0.72, while that for patient households is between 0.94 – 0.97.

positive levels of debt in equilibrium without going delinquent. Finally, we estimate the shape parameter of the haircut distribution to be 1.645. This value implies that, on average, about 60% of delinquent debt will be forgiven within one year. This high haircut rate helps the model match the low delinquency hazard rate of about 40%. Moreover, it is consistent with lenders selling their delinquent debt to debt collectors for a low price relative to the face value of debt.

**Table 7: Model Parameters**

Parameter description	Parameter	Value	Calibration Source
Risk-free rate	$r_f$	2%	Standard value
Arrival rate of income shocks	$\lambda_y$	0.348	PSID income moments
Persistence of income shocks	$\rho$	0.756	PSID income moments
Volatility of income shocks	$\sigma_{\epsilon,y}$	0.615	PSID income moments
Expenditure shock mean	$\mu_e$	0.08	MEPS expenditure moments
Expenditure shock volatility	$\sigma_e$	1.61	MEPS expenditure moments
Discount factor	$\beta$	0.857	Indirect inference (Table 6)
Disutility of delinquency	$\xi$	0.246	Indirect inference (Table 6)
Haircut power law shape	$\chi$	1.645	Indirect inference (Table 6)

*Notes:* This table presents the targeted data moments as well as the model-implied moments of the estimated model. The last row reports the main regression coefficient from Section 2 and the estimand in the model.

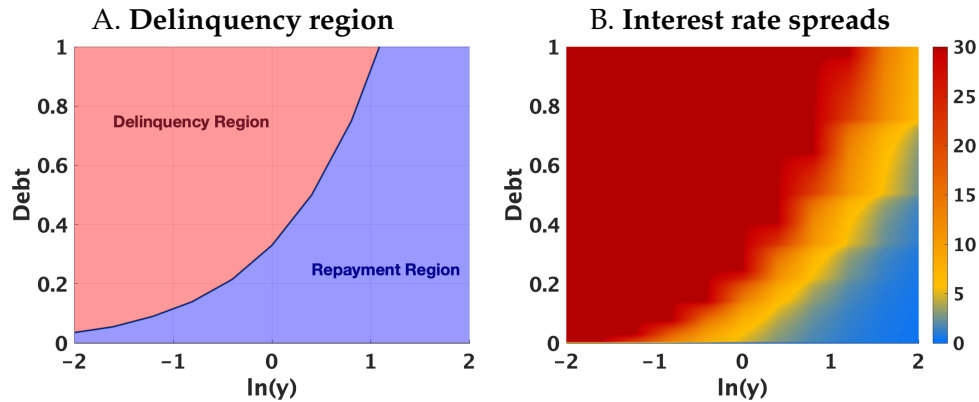

### 3.5 Equilibrium properties

We solve the model globally and compute the stationary distribution across income and debt levels. Panel A of Figure 8 presents the regions of the state space where households choose to repay or renege on their debt obligations.<sup>35</sup> In general, lower income implies a lower debt threshold, above which households do not repay their debt. Because the utility function is concave, low-income households are more tempted not to repay their debt and increase their contemporaneous consumption. As a result, low-income households cannot maintain a high level of debt.

The probability of delinquency affects the interest rate spreads households face. Panel B of Figure 8 presents the interest rate spreads households face in equilibrium. The horizontal axis is the current income level of the households, and the vertical axis represents the debt

<sup>35</sup>While the upper limit of debt in Figure 8 is 1, we solve the model with the upper limit of debt being 6. The share of households with debt level above 1 is very small.

**Figure 8: Equilibrium properties**

*Notes:* The left panel presents the regions where households choose to repay their debt or go delinquent. The right panel presents the interest rate spreads households pay as a function of promised repayment. The interest rate spread is capped for illustration purposes at 30%, so the dark share of red represents interest rate spreads above that cap.

obligations promised to be repaid in the following period. Because high-income households are less likely to renege on their debt obligations, they face lower interest rate spreads. In a similar fashion, low-income households face very high interest rate spreads.

The interest rate schedule faced by low-income households effectively limits their access to credit. Policies that reduce the delinquency probability of these households expand their credit access by lowering these interest rate spreads. In the next section we study the effects of one such policy: the expansion of Medicaid.

**Model Abstractions.** Our model abstracts away from several aspects of health, which will generally make our policy counterfactual analysis conservative. First, we do not model households' "health." Therefore, our welfare calculations reflect improvements in financial health rather than physical health. In reality, the welfare benefits from improved physical health are also likely large, as Medicaid expansions significantly reduced both child and adult mortality ([Goodman-Bacon, 2018, 2021b](#); [Miller et al., 2021](#)).

Second, our model does not feature moral hazard in terms of risky health behaviors or use of medical services. Prior analyses of the ACA's Medicaid expansion do not find effects on risky behaviors (e.g., smoking and lack of exercise, [Simon, Soni and Cawley, 2017](#)).

However, research generally estimates moderate moral hazard responses in terms of overall health expenditures (Manning et al., 1987; Finkelstein et al., 2012; Garthwaite et al., 2019), although a recent analysis of the Medicaid expansion under the ACA finds no impact on total (pre-insurance) medical expenditures (Shupe, 2023). Because households do not increase total medical expenditures in our model, the model likely understates the borrowing response. While the additional costs of the expansion that would arise from increased expenditure are not included in our welfare calculation, these costs should be weighed against the welfare gains from improved physical health.

Third, income and medical expenditure shocks are uncorrelated in our model. In reality, the health events resulting in large medical expenditures may reduce income and employment (Dobkin et al., 2018; Stepner, 2019). If expanding Medicaid improves access to care and reduces the likelihood of major illnesses, then our model would understate the financial benefits from higher income associated with these health improvements. It likely also understates the borrowing response, as avoiding low-income states of the world improves credit access.

## 4 The Effect of Medicaid Expansion on Debt and Welfare

In this section, we study how the expansion of Medicaid shapes the distribution of debt across households in the economy and study its welfare implications. We start by studying the channels through which health insurance policy can affect households' accumulation of debt. We then study the effect of Medicaid expansion in our model.

### 4.1 Theoretical analysis

We model the expansion of health insurance as a change in the out-of-pocket share of medical expenditure that households of different income levels face,  $o(y)$ . A more generous health insurance policy corresponds to a reduction in the out-of-pocket share that different households pay for medical shocks.

Health insurance policy affects households' accumulation of credit card debt in several ways, both directly and indirectly. There are two direct effects of the policy. First, a more generous health insurance is increasing households' disposable income. As a result, household debt levels decline. Second, the insurance against medical expenditure shocks reduces

delinquency rates. When a household in delinquency receives a medical expenditure shock, its additional debt is not counted as credit card debt but rather as medical debt. When a household is not in delinquency, receiving a medical shock may result in more borrowing to cover that expenditure. The decline in delinquency rates leads to a substitution from medical debt to credit card debt. Overall, the direct effects of the policy reduce overall debt levels, but may result in larger levels of credit card debt.

To study the indirect channels of the policy, consider the household's optimality condition with respect to debt accumulation, which is given by

$$u'(c) \frac{\partial (q(b', y)b')}{\partial b} = \beta \mathbb{E} \mathbb{1}_{V^r \geq V^d} u'(c(b' + o(y')m', y')) + \beta \mathbb{E} \mathbb{1}_{V^r < V^d} V_1^d (b' + o(y')m', y') \quad (10)$$

The household equated the benefits from borrowing (LHS) to the utility costs of borrowing (RHS). By increasing debt obligations,  $b'$ , the household increases its current funds by  $\frac{\partial (q(b', y)b')}{\partial b}$ . Note that the household internalizes how its borrowing decision affects the interest rate it pays on debt. There are two potential costs of borrowing. If the household repays its debt in the following period ( $V^r \geq V^d$ ), the marginal cost of debt obligations is simply the marginal utility of consumption. Alternatively, if the household goes delinquent ( $V^d > V^r$ ), the household's cost of debt obligations is  $\frac{\partial V}{\partial b}$ .

The first indirect channel through which social insurance affects household debt is a reduction in the *precautionary savings motive*. A reduction in  $o(y')$  reduces the volatility of out-of-pocket medical expenditure,  $o(y')m'$ . This results in a lower volatility of future consumption. If the utility function features prudence ( $u'''(\cdot) > 0$ ), as it does in our calibration, then such reduction in volatility results in a smaller cost of borrowing. The reduction in the marginal cost of borrowing induces households to take on more debt. That is, through the precautionary savings channel, social insurance raises household debt levels.

The second indirect channel is the *debt aversion* channel. Borrowing is more costly in the states where households repay their debt obligations. Debt is less costly in the delinquency state as households expect to pay it only in the future, and after a haircut. A more generous insurance policy raises the probability of repayment,  $\mathbb{E} \mathbb{1}_{V^r \geq V^d}$ , as medical expenditures that

would have pushed households into delinquency are now partially insured. The increase in the repayment probability deters households from taking on debt, as they are more likely to repay it. Therefore, through the debt aversion channel, social insurance reduces household debt levels.

Both the precautionary savings motive and the debt aversion channels do not depend on lenders changing their behavior. That is, they do not depend on the supply side of loans. We refer to the combined effect of these two channels as the *credit demand* channel.

The final indirect channel is the *credit supply* channel. The reduction in delinquency probability induces lenders to lower interest rate spreads,  $q(b', y)$ . This raises the benefits from taking on more debt obligations  $b'$ . For each unit of consumption promised to be repaid in the following period, households receive more units of consumption in the current period. This induces households to increase their debt obligations. So, through the credit supply channel, social insurance increases household debt levels.

Overall, the effect of social insurance on the aggregate level of household debt is ambiguous. We now turn to study the expansion of Medicaid in our model and quantitatively assess the strength of the different channels.

## 4.2 Medicaid expansion

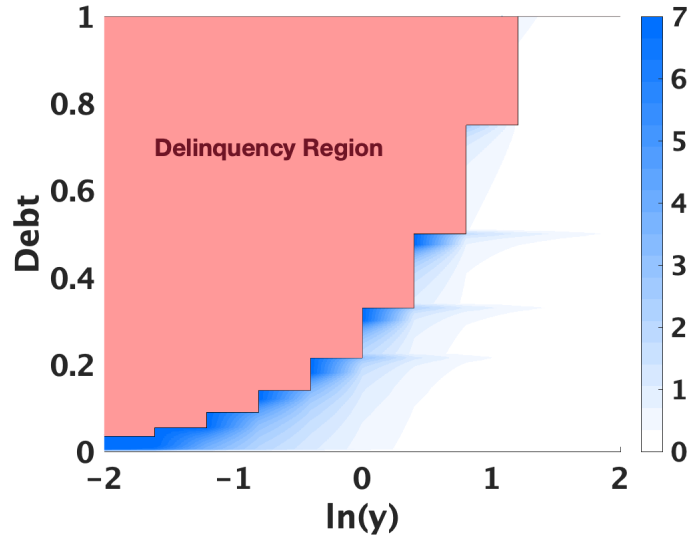

Our benchmark specification assumes that the share of households covered by Medicaid insurance is log-linear in household income percentile. Low-income households are more likely to be covered by Medicaid. In this section, we consider a policy that mimics the expansion of Medicaid as part of the ACA in the data. Following the results in the left panel of Figure 3, we change the coefficients of the Medicaid coverage function so that the share of households insured by Medicaid follows the post-expansion pattern across states. We maintain the share of households insured by non-Medicaid insurance the same.

The resulting Medicaid insurance approximation implies that an additional 4.5 percent of households are covered by Medicaid. We solve the model and compute the stationary distribution, as well as the transition dynamics towards the new stationary distribution. We assume the out-of-pocket share of the Medicaid policy remains unchanged at a rate of 6.8%.

The expansion of Medicaid reduces the delinquency probability of households, as health

expenditure shocks that would push households into the delinquency region are not partially covered by their health insurance. This results in lower interest rate spreads in equilibrium. The reduction in equilibrium spreads as a result of the policy is plotted in Figure 9. Households who are close to the delinquency region are now facing lower interest rate spreads relative to the pre-expansion interest rate spreads.

**Figure 9:** Reduction in interest rate spreads due to policy

*Notes:* This figure presents the reduction in equilibrium interest rate spreads in percentage points.

The reduction in interest rate spreads affects low-income households who tend to be close to the default frontier. High-income households, who often do not hold any debt and are not covered by Medicaid, are less affected by the expansion of Medicaid.

The expansion of Medicaid in our model leads to a long-run increase of 4.7% in credit card debt. Our model allows us to decompose the credit card impact into the three theoretical channels we laid out in the previous subsection: the direct channel, the credit demand channel, and the credit supply channel. The decomposition results are summarized in the top panel of Table 8.

To get the direct impact of Medicaid expansion, we keep the debt pricing schedule as well as the policy functions of households as they are prior to the expansion. The only change we consider here is the change to the out-of-pocket share of medical expenditure,  $o(y)$ . The direct impact of the policy on debt is a modest increase of 0.24% in the aggregate level of credit card

**Table 8:** Decomposing the effect of Medicaid expansion

<b>Not budget neutral</b>				
	Total impact	Direct impact	Credit demand	Credit supply
Credit card debt	+4.70%	+0.24%	-7.95%	+12.4%
Total welfare	+0.58%	+0.43%	+0.004%	+0.15%
<b>Budget neutral</b>				
	Total impact	Direct impact	Credit demand	Credit supply
Credit card debt	+5.04%	+0.24%	-7.78%	+12.58%
Total welfare	+0.47%	+0.32%	+0.004%	+0.15%

debt.

The credit demand channel is computed by keeping the debt pricing schedule at its levels prior to the expansion of Medicaid but allowing households to re-optimize given the original pricing schedule. The credit demand channel reduces the aggregate-level credit by 7.95%. This implies that the debt aversion channel is much stronger than the precautionary savings channel.

Finally, the credit supply channel is computed by also updating the debt pricing schedule so that financial intermediaries make zero profits. The reduction in interest rates, which can be seen in Figure 9, leads to a large increase in credit card debt. The credit supply channel raises the aggregate level of credit card debt by 12.4%, leading to an overall increase of aggregate credit card debt across households.

Our model also allows us to study the welfare impact of the policy. We first consider the policy when budget is not neutral, so that no tax is levied on households. The model is useful in studying how important the different channels are in driving welfare, as well as comparing the welfare benefits across different households. Following Chatterjee et al. (2007), we calculate welfare by computing the percentage drop in consumption in all periods following the expansion of Medicaid that would make households indifferent between implementing and not implementing the policy. On average, the policy leads to a welfare benefit of 58 basis points in consumption-equivalent terms. That is, the average household in the economy is willing to incur a 0.58% drop in consumption in all periods so that Medicaid expansion remains in place.

We decompose the effects of the Medicaid expansion to the three channels. The results are

presented in the second row of Table 8. The reduction in out-of-pocket medical expenditure accounts for the majority of welfare benefits. This effect is expected: we assume households do not pay any cost to implement the policy. The direct channel accounts for 74% of the welfare gains.

The credit demand channel has only a negligible welfare effect. This is simply the envelope theorem. Households were optimizing their borrowing decision prior to the policy. So adjusting their borrowing decision following the policy can only lead to second-order welfare gains.

Unlike the credit demand channel, the credit supply channel leads to sizable welfare benefits: 0.15% out of a total of 0.58%. That is, 26% out of the total welfare gains of the expansion of Medicaid can be attributed to the reduction in interest rate spreads households pay. This result suggests policymakers should take into account the impact of social insurance policies on the supply of credit. Disregarding the effect of social insurance on the supply of credit understates its welfare benefits.

Finally, we consider an alternative in which the policy is financed through a uniform tax levied on all households. Medicaid expansion reduces uncompensated medical care. We choose the uniform tax rate so that the tax revenues are equal to the cost of enacting the policy net of the reduction in uncompensated medical care.<sup>36</sup> The resulting uniform tax is 0.08%. The bottom panel of Table 8 presents the effect of the budget-neutral Medicaid expansion on debt and welfare.

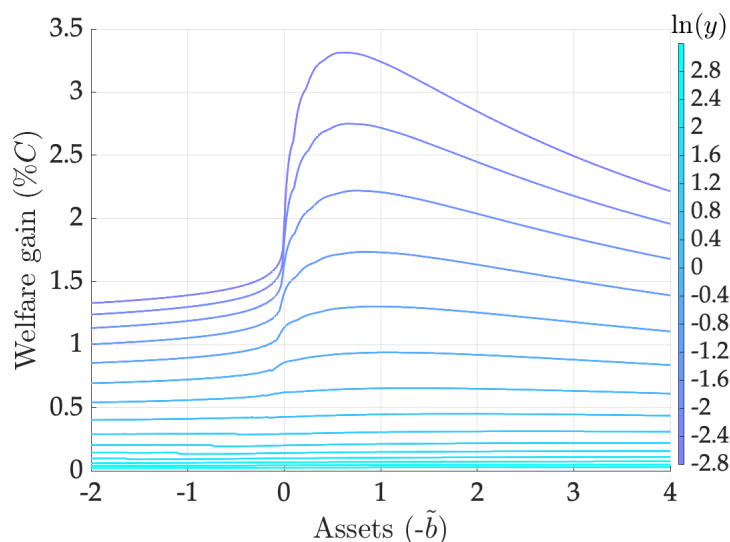

The aggregate impact on credit card debt is slightly larger under the budget-neutral policy. Households' disposable income is lower as a result of the tax, so their debt level goes up. The direct welfare benefits from the program fall from 0.58% to 0.47%. Note, however, that the welfare benefits attributed to the credit supply channel remain approximately the same. The credit supply channel amplifies the direct welfare benefits of Medicaid expansion by 50%.

Figure 10 presents the net welfare gains from the budget-neutral policy. We see that the majority of the welfare gains come from low-income non-delinquent households. The less income a household have, the more medical insurance they receive, and the higher their wel-

---

<sup>36</sup>Uncompensated medical care is defined as the sum of unpaid out-of-pocket medical bills net of the market value of medical debt due to unpaid medical bills.

**Figure 10:** Heterogeneous welfare effect of budget-neutral Medicaid expansion

*Notes:* This figure presents the welfare gains (in consumption equivalence terms) from Medicaid expansion across the state space. The lighter shades of blue correspond to higher income households. Negative levels of assets correspond to positive debt levels.

fare gains from the policy. It is worth noting that even high-income households do not suffer welfare losses despite the increase in their income tax. The top 5% of the income distribution obtain welfare gains of between 0.01% – 0.1%. These high-income households value more the insurance they gain from the policy than the income tax they pay to finance it.

## 5 Conclusion

This paper investigates how social insurance affects household debt. We exploit heterogeneity in the impact of the staggered expansions of Medicaid as a source of quasi-experimental variation in households' access to health insurance. Using a difference-in-difference design, we estimate that a 1 percentage point increase in health insurance coverage leads to a 0.56% increase in credit card debt. Consistent with credit supply increasing in response to expanded Medicaid, we find that credit limits rises and overall utilization decreases. In support of improved financial resilience driving this rise in credit supply, we show that delinquency remains stable despite the increase in debt and that debt in collections decreases. Credit scores increase as well.

Our paper builds on prior empirical work by focusing on general equilibrium channels

and both macroeconomic and distributional outcomes. We develop a heterogeneous-agent model in which households face permanent and transitory differences in their income, health expenditure shocks, and incomplete markets. Households incur debt both by choosing how much to borrow on a credit card and as a result of health expenditure shocks. Using the model, we explore the impact of expanding health insurance.

While insurance can help households avoid taking on debt when experiencing adverse events such as job loss and illness, it can also increase borrowing by enhancing households' financial resilience. Insurance softens the financial impact of adverse events, making it easier to avoid default or states of the world in which consumption is extremely low. In doing so, insurance can dampen households' precautionary savings motive and raise lenders' expected returns, increasing both credit demand and supply. Our empirical evidence suggests that these credit demand and supply channels dominate the direct impact on borrowing in equilibrium. Our model is also able to match this finding. Our findings suggest that institutions such as social insurance can have an important impact on the quantity and distribution of household debt as well as welfare.

## A Additional Figures and Tables

**Table A.1:** Revolving Credit Card Balances (Adding Flexible Income Controls)

	(1)	(2)	(3)	(4)
$\text{NewElig}_{zs} \times \text{Post}_{st}$	0.557*** (0.116)	0.456*** (0.101)	0.408*** (0.086)	0.404*** (0.087)
$\log(\text{AGI}_{zcs})$	0.096*** (0.020)	0.133*** (0.016)	0.160*** (0.015)	0.177*** (0.018)
Obs	372,218	372,218	372,218	372,218
R2	0.957	0.957	0.957	0.957
Percentile Controls	None	Quartiles	Deciles	5th, 10th, ... 95th

*Notes:* This table reports results from regressions that control for additional moments from the ZIP code's income distribution for our main outcome of interest: log revolving credit card balances. Column 1 reproduces our baseline specification Equation (1). Column 2 adds controls for quartiles (i.e., the 25th, 50th, and 75th percentile of the ZIP code's income distribution). Column 3 instead uses deciles (10th, 20th, ..., 90th) percentiles. Column 4 uses 19 percentiles ranging from the 5th to 95th percentile. Standard errors are clustered by state. Nominal variables are CPI-adjusted to be in terms of 2020 dollars. Statistical significance: 10%\*, 5%\*\*\*, and 1%\*\*\*.

Window	-3 to +6 years		-3 to +5 years		-3 to +4 years	
Stacked	No	Yes	No	Yes	No	Yes

*Notes:* This table reports results from estimating the "stacked" version of the DID in Equation (1). Columns 1 and 2 use the sub-sample of observations whose states expanded in 2014 using data from 3 years before to 6 years after expansion (the window). Columns 3 and 4 expand the sample to observations whose states expanded in 2015 or earlier but use a narrower window of 3 years before to 5 years after. Columns 5 and 6 expand the sample to include observations whose states expanded in 2016 or earlier, but restrict the window to 3 years before to 4 years after expanding. Each panel these six regressions for different outcome variables. To facilitate comparisons, the odd-numbered columns display non-stacked regression results for the sub-samples used in the stacked regressions. Each specification uses county-time and ZIP code fixed effects and controls for logged ZIP-level average adjusted gross income (AGI), whose coefficient is omitted above for brevity. Standard errors are clustered by state. Nominal variables are CPI-adjusted to be in terms of 2020 dollars. Statistical significance: 10%\*, 5%\*\*, and 1%\*\*\*.

### A.3 Delinquency Duration

Figure A.1: Duration of Delinquency

Notes: This figure plots the fraction of people that are delinquent one to seven years later (after an initial delinquency). Here, delinquency means that a person has debt 90 or more days past due or debt in collections. We use a subsample of people that are continuously observed for at least three years (totaling 2,306,609 unique individuals).

Table A.8: Persistence of Delinquency

Years	Percentage of People Still Delinquent
0	100%
1	38.9%
2	18.6%
3	9.46%
4	5.03%
5	2.71%
6	1.52%
7	0.83%
8	0.45%
9	0.23%
10	0.11%
<b>Average Duration:</b>	<b>1.78 years</b>

Notes: This table reports the fraction of people that are delinquent zero to 10 years later (after an initial delinquency). Here, delinquency means that a person has debt 90 or more days past due or debt in collections. We use a subsample of people that are continuously observed for at least three years (totaling 3,473,613 unique individuals).

## B Eligibility Estimation

This appendix describes how we generate a measure of Medicaid eligibility at the ZIP  $\times$  year level.

**Data:** We use the following datasets from 2009 to 2016:

1. IRS SOI: ZIP-code level individual income tax statistics
2. KFF: Medicaid eligibility limits
3. ACS: joint distribution of income and household size
4. KFF: Medicaid expansion date data

### B.1 Estimand

We want estimates of the fraction of adults eligible for Medicaid in year  $t$  and ZIP  $z$ . Let  $E$  denote the event a household is eligible for Medicaid. Denote the probability that a household is eligible in  $(t, z)$  by  $P_{tz}(E)$ .  $P_{tz}(E) = P(E|t, z)$ . The probability that a household of size  $n$  is eligible depends on the probability that its income is below the relevant cutoff  $c_{tz}^n$ . We can write out the probability above into the sum of probabilities for these different cases using the law of iterated expectations:

$$P_{tz}(E) = P_{tz}(y \leq c) = \sum_{n=1}^N P_{tz}(y \leq c_{tz}^n | c = c_{tz}^n) P(c = c_{tz}^n)$$

where  $y$  is income and  $c_{tz}^n$  is the eligibility cutoff for a household of size  $n$  in  $\{z, t\}$ . We can rewrite each term using Bayes' rule to get

$$P_{tz}(y \leq c_{tz}^n | c = c_{tz}^n) P(c = c_{tz}^n) = P_{tz}(c = c_{tz}^n | y \leq c_{tz}^n) P(y \leq c_{tz}^n).$$

The first term is the probability that a household is of a given size:

$$P_{tz}(c = c_{tz}^n | y \leq c_{tz}^n) = P_{tz}(\tilde{N} = n | y \leq c_{tz}^n) = g_{tz}(n | y \leq c_{tz}^n)$$

where  $g_{tz}$  is the probability mass function of a household size conditional on income being below the relevant threshold. The second term  $P(y \leq c_{tz}^n)$  is the probability that the household's income is below the threshold. Let  $F_{tz}(\cdot)$  denote the cumulative distribution function of income in  $\{t, z\}$ . Then

$$P(y \leq c_{tz}^n) = F_{tz}(c_{tz}^n).$$

**Household Size Notation:** Households of size two may comprise either a head and a dependent or a head and a non-dependent (e.g., a parent and child versus a childless couple). The eligibility thresholds can differ across these situations. To capture both, we use 2 to indicate a household with a head and a dependent and  $2^*$  to indicate a two-person household with no dependents. Let  $n$  denote household size. We write  $n \in n\{1, 2, 2^*, 3, 4, \dots, N\}$ , where  $N$  is the largest observed household size.

**Note on Cutoffs:** Income cutoffs vary over time because of changes in the threshold and federal poverty line. They also differ across states; specifically, Alaska and Hawaii generally have higher thresholds in each year.

## B.2 Estimation

We estimate  $P_{tz}(E)$  using the following steps:

1. We procure the number of tax returns and annual gross income by income bins for each ZIP code and year using IRS SOI.
2. Then, we interpolate the CDF  $\hat{F}_{tz}(\cdot)$  of income between the known bins. With that, we estimate  $\hat{F}_{tz}(c_{tz}^n)$  where  $c_{tz}^n$  is obtained from Medicaid eligibility limits. Note that this equals the second term of the probability,  $P(y \leq c_{tz}^n)$ . We generate this for  $n \in N$  household sizes where  $N$  is defined above.
3. We keep one observation per ZIP and year.
4. We use the ACS data to calculate  $P(\tilde{N} = n | y \leq c_{tz}^n)$  for each  $n$ . We do this using income and household size information available by ZIP code and year. Note that this equals the first term of the probability,  $g_{tz}(n | y \leq c_{tz}^n)$ .

5. We can calculate the probability that a household of size  $n$  is eligible for Medicaid by multiplying the first and second terms for each  $n$ .
6. Then,  $P_{tz}(E)$  is equal to the sum of the probabilities calculated in the step above.

## C Mathematical Appendix

### C.1 Proof of Proposition 1 - Uniqueness of Debt Pricing Schedule

The debt pricing schedule is given by

$$q(b', y) = \frac{1}{1+r_f} [1 - \mathbb{E}(d(b' + o(y')m', y'))] \\ + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1 - \delta')q((1 - \delta')(b' + o(y')m'), y')].$$

Let  $B(\mathbb{R}^2)$  be the set of bounded functions  $q : \mathbb{R}^2 \rightarrow \mathbb{R}$ . Define the operator  $T : B(\mathbb{R}^2) \rightarrow B(\mathbb{R}^2)$  as follows:

$$T(q)(b', y) = \frac{1}{1+r_f} [1 - \mathbb{E}(d(b' + o(y')m', y'))] \\ + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1 - \delta')q((1 - \delta')(b' + o(y')m'), y')]. \quad (11)$$

We will use Blackwell's sufficient conditions to show that  $T$  is a contraction mapping with modulus  $\frac{1}{1+r_f} < 1$ .

**Monotonicity.** Suppose  $q_1(b', y) \geq q_2(b', y)$  for all  $b'$  and  $y$ . Then,

$$T(q_1)(b', y) = f(b', y) + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1 - \delta')q_1((1 - \delta')(b' + o(y')m'), y')] \\ \geq f(b', y) + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1 - \delta')q_2((1 - \delta')(b' + o(y')m'), y')] \\ = T(q_2)(b', y)$$

where  $f(b', y) = \frac{1}{1+r_f} [1 - \mathbb{E}(d(b' + o(y')m', y'))]$ . The first inequality follows from the fact that  $d(b' + o(y')m', y')(1 - \delta') \geq 0$  for all  $(b', y')$ .

**Discounting.** We have that

$$\begin{aligned}
T(q+a)(b', y) &= f(b', y) + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1-\delta') [q((1-\delta')(b' + o(y')m'), y') + a]] \\
&= T(q)(b', y) + \frac{1}{1+r_f} \mathbb{E} [d(b' + o(y')m', y')(1-\delta')] a \\
&\leq T(q)(b', y) + \frac{1}{1+r_f} a,
\end{aligned}$$

where the last inequality follows from  $d(b' + o(y')m', y')(1-\delta') \in [0, 1]$  for all  $(b', y')$ . Therefore,  $T$  is a contraction mapping with modulus  $\frac{1}{1+r_f}$ . Hence, the debt pricing schedule  $q(b', y)$  exists and is unique, given a delinquency policy function  $d(\tilde{b}', y)$ .

## C.2 Moments of Income Process

Suppose that the income process takes the following form:

$$\ln y_t = \begin{cases} \rho \ln y_{t-1} + \epsilon_t & \text{w.p. } \lambda, \\ \ln y_{t-1} & \text{w.p. } 1 - \lambda, \end{cases} \quad (12)$$

where  $\epsilon_t$  follows a Normal distribution with standard deviation  $\sigma$ . We calibrate the structural parameters  $\{\rho, \sigma, \lambda\}$  to match the persistence of income, as well as the standard deviation and kurtosis of income changes. Since the PSID reports household-level income every two years, we match the 2-year auto-correlation of income, as well as the standard deviation and kurtosis of 2-year income changes.

**Proposition 2.** *The income process admits the following moments:*

$$\begin{aligned}
\text{acorr}_2(\ln y_t) &= \frac{\mathbb{E} [\ln y_t \ln y_{t+2}]}{\text{var}(\ln y_t)} = (1 - \lambda + \lambda\rho)^2, \\
\text{var}(\Delta \ln y_t) &= \mathbb{E} [(\ln y_{t+1} - \ln y_t)^2] = 2(1 - (1 - \lambda + \lambda\rho)) \text{var}(\ln y_t), \\
\text{var}(\Delta_2 \ln y_t) &= \mathbb{E} [(\ln y_{t+2} - \ln y_t)^2] = 2(1 - (1 - \lambda + \lambda\rho)^2) \text{var}(\ln y_t), \\
\text{kurt}(\Delta \ln y_t) &= \frac{3}{4} \frac{1}{\lambda} \left( (1 - \rho)^4 + 2(1 - \rho)^2(1 - \rho^2) + (1 - \rho^2)^2 \right) \frac{(1 + \rho)^2}{(1 - \rho^2)^2}, \\
\text{kurt}(\Delta_2 \ln y_t) &= \frac{2(1 - \lambda) K_\Delta V_\Delta^2 + \lambda^2(3(\rho^2 - 1)^4 V_y^2 + 3(1 + \rho^4)\sigma^4 + 6\rho^2\sigma^4 + 6(\rho^2 - 1)^2(1 + \rho^2 V_y \sigma^2))}{V_{\Delta_2}^2},
\end{aligned}$$

where  $V_y = \text{var}(\ln y_t)$ ,  $V_\Delta = \text{var}(\Delta \ln y_t)$ ,  $V_{\Delta_2} = \text{var}(\Delta_2 \ln y_t)$  and  $K_\Delta = \text{kurt}(\Delta \ln y_t)$ .

*Proof.* **1. Proof of 2-year auto-correlation.**

$$\mathbb{E} [\ln y_t \ln y_{t+2}] = (1 - \lambda)^2 \text{var}(\ln y_t) + 2\lambda(1 - \lambda)\rho \text{var}(\ln y_t) + \lambda^2 \rho^2 \text{var}(\ln y_t).$$

Rearranging we have

$$\frac{\mathbb{E} [\ln y_t \ln y_{t+2}]}{\text{var}(\ln y_t)} = (1 - \lambda)^2 + 2(1 - \lambda)\rho\lambda + \lambda^2 \rho^2 = (1 - \lambda + \lambda\rho)^2.$$

**2. Proof of 1-year income change variance.**

$$\mathbb{E} [(\ln y_{t+1} - \ln y_t)^2] = 2 \text{var}(\ln y_t) - 2\mathbb{E} (\ln y_{t+1} \ln y_t).$$

Similarly to how we proved the 2-year auto-correlation, we have that

$$\mathbb{E} (\ln y_{t+1} \ln y_t) = (1 - \lambda + \lambda\rho) \text{var}(\ln y_t).$$

So we obtain

$$\mathbb{E} [(\ln y_{t+1} - \ln y_t)^2] = 2(1 - (1 - \lambda + \lambda\rho)) \text{var}(\ln y_t).$$

**3. Proof of 2-year income change variance.**

$$\mathbb{E} [(\ln y_{t+2} - \ln y_t)^2] = 2 \text{var}(\ln y_t) - 2\mathbb{E} (\ln y_{t+2} \ln y_t).$$

We have that

$$\begin{aligned} \mathbb{E} (\ln y_{t+2} \ln y_t) &= (1 - \lambda)\mathbb{E} (\ln y_{t+1} \ln y_t) + \lambda\rho\mathbb{E} (\ln y_{t+1} \ln y_t) \\ &= (1 - \lambda + \lambda\rho)\mathbb{E} (\ln y_{t+1} \ln y_t). \end{aligned}$$

Combining everything we have

$$\mathbb{E} [(\ln y_{t+2} - \ln y_t)^2] = 2 (1 - (1 - \lambda + \lambda\rho)^2) \text{var}(\ln y_t).$$

4. **Proof of 1-year income change kurtosis.** Let's start from the unconditional variance,  $\text{var}(\ln y_t)$ . From equation (12), we have

$$\text{var}(\ln y_t) = \lambda (\rho^2 \text{var}(\ln y_t) + \sigma^2) + (1 - \lambda)\text{var}(\ln y_t).$$

Rearranging we obtain

$$\text{var}(\ln y_t) = \frac{1}{1 - \rho^2} \sigma^2.$$

Now we derive the kurtosis:

$$\begin{aligned} \mathbb{E} (\Delta \ln y_t)^4 &= \lambda \mathbb{E} ((\rho - 1) \ln y_t + \sigma \epsilon)^4 \\ &= \lambda \left[ (\rho - 1)^4 \mathbb{E}(\ln y_t)^4 + 6(1 - \rho)^2 \mathbb{E}(\ln y_t)^2 \sigma^2 + 3\sigma^4 \right] \\ &= \lambda \left[ (1 - \rho)^4 + 2(1 - \rho)^2(1 - \rho^2) + (1 - \rho^2)^2 \right] \frac{1}{(1 - \rho^2)^2} 3\sigma^4 \end{aligned}$$

where we've used

$$\mathbb{E}(\ln y_t)^2 = \text{var}(\ln y_t) = \frac{1}{1 - \rho^2} \sigma^2,$$

and we can obtain  $\mathbb{E}(\ln y_t)^4$  as follows

$$\mathbb{E}(\ln y_t)^4 = (1 - \lambda)\mathbb{E}(\ln y_t)^4 + \lambda \left[ \rho^4 \mathbb{E}(\ln y_t)^4 + 6\rho^2 \frac{1}{1 - \rho^2} \sigma^4 + 3\sigma^4 \right]$$

so that

$$\mathbb{E}(\ln y_t)^4 = \frac{1}{1 - \rho^4} \left( \frac{2\rho^2}{1 - \rho^2} + 1 \right) 3\sigma^4 = \frac{1}{(1 - \rho^2)^2} 3\sigma^4$$

Finally we get that

$$\text{Kurt}(\Delta \ln y_t) = \frac{\mathbb{E}(\Delta \ln y_t)^4}{\text{var}^2(\Delta \ln y_t)} = \frac{3}{4\lambda} \left[ (1 - \rho)^4 + 2(1 - \rho)^2(1 - \rho^2) + (1 - \rho^2)^2 \right] \frac{(1 + \rho)^2}{(1 - \rho^2)^2}$$

where we've used  $Var(\Delta \ln y) = 2\lambda \frac{(1-\rho)}{1-\rho^2} \sigma^2 = 2\lambda \frac{1}{1+\rho} \sigma^2$ .

### 5. Proof of 2-year income change kurtosis.<sup>37</sup>

$$\begin{aligned} \mathbb{E}(\ln y_{t+2} - \ln y_t)^4 &= 2(1-\lambda)\lambda \mathbb{E}((\rho-1)\ln y_t + \sigma\epsilon)^4 + \lambda^2 \mathbb{E}((\rho^2-1)\ln y_t + \rho\sigma\epsilon_1 + \sigma\epsilon_2)^4 \\ &= 2(1-\lambda)\mathbb{E}(\Delta \ln y)^4 + \lambda^2 \mathbb{E}((\rho^2-1)\ln y_t + \rho\sigma\epsilon_1 + \sigma\epsilon_2)^4 \end{aligned}$$

Let's expand the second term:

$$\mathbb{E}((\rho^2-1)\ln y_t + \rho\sigma\epsilon_1 + \sigma\epsilon_2)^4 = (\rho^2-1)^4 3V_y^2 + (1+\rho^4)3\sigma^4 + 6\rho^2\sigma^4 + 6(\rho^2-1)^2(1+\rho^2)V_y\sigma^2,$$

where we've used  $kurt(\ln y_t) = 3$ . Combining this expression with the first term we obtain

$$\begin{aligned} \mathbb{E}(\ln y_{t+2} - \ln y_t)^4 &= 2(1-\lambda) K_\Delta V_\Delta^2 + \lambda^2(3(\rho^2-1)^4 V_y^2 + 3(1+\rho^4)\sigma^4 + 6\rho^2\sigma^4 + 6(\rho^2-1)^2(1+\rho^2)V_y\sigma^2). \end{aligned}$$

Together with the definition of kurtosis,  $kurt(\Delta_2 \ln y_t) = \frac{\mathbb{E}(\ln y_{t+2} - \ln y_t)^4}{(\mathbb{E}(\ln y_{t+2} - \ln y_t)^2)^2}$ , we proved the desired expression.

□

---

<sup>37</sup>Since this moment involves extensive algebra, we confirmed via simulations that our formula is correct.
