How Elastic is the Job Creation Curve?

Ben Sand§

March, 2011

Abstract

We use search and bargaining theory to develop an empirically tractable specification of the job creation curve and to derive an instrumental variable strategy to estimate and test its validity. We estimate the job creation curve using city level observations for 1970-2007. We find that U.S. city-industry level labor market outcomes conform well to restrictions implied by search and bargaining theory. Using 10-year differences, we estimate the elasticity of the job creation curve with respect to wages to be -0.3. We interpret this relatively low elasticity as reflecting a low propensity for individuals to become entrepreneurs when labor costs decline.

Introduction

The evaluation of policies or institutions that change labor costs requires a clear understanding of how such changes affect employment. Discussions of numerous policies, including payroll taxes, job security legislation, minimum wages and policies related to worker benefits are commonly framed in terms of whether they will “kill” jobs or, if cut, help create new ones.\(^1\) As a recent example, in debates about stagnant employment outcomes as economies emerge from recession, many analysts have argued that cutting labor costs is the key to re-starting employment growth. Embedded in such a claim is the view that higher labor costs substantially reduce aggregate employment. The evidence on this, however, remains mixed. Many of the studies that examine the direct impacts of labor cost shifts – such as induced by payroll tax changes – find only modest impacts on aggregate employment (Blau and Kahn, 1999), implying rather inelastic labor demand curves. On the other hand, studies of regional responses to supply shocks tend to find quite small wage impacts, implying very elastic labor demand curves (Blanchard and Katz, 1992; Krueger and Pischke, 1997).\(^2\) Further variation in estimates arises because different studies use different measures of employment outcomes (either employment rates or employment levels), often without a clear reference to theory to support their choice. Thus, policy makers face a confusing array of predictions about the employment impacts of policies that affect labor costs either directly or indirectly.

Attempts to provide estimates of the effects of labor costs on employment must deal with the inherent endogeneity problem stemming from the fact that wages and employment are jointly determined. In this paper, we provide estimates of the effects of labor costs on employment using a search and bargaining model to help guide and motivate our empirical strategy. We adopt this modeling perspective because it offers new insights regarding how to estimate the effects of labor costs on employment and it imposes simple testable implications which we can evaluate with available data. In addition, the model provides a potential explanation for disparities among earlier estimates of labor demand elasticities related to the use of different forms of variation and different dependent variables.

In search and bargaining models, labor demand is determined by an equilibrium relationship known as the job creation curve. This curve reflects employers’ comparisons of the expected cost to the expected benefit of opening and maintaining a vacancy. With unrestricted entry, this implies that a rise in wages (which reduces the benefits of a filled job for the firm), must be offset by a decline in the tightness of the labor market, i.e., a decline in the employment rate. This equilibrium relationship is the job creation curve, and it is the slope of this curve which we are interested in.

---

\(^1\)For example, the California Chamber of Commerce releases an annual list of “job killer” bills which they claim identifies legislation that will “decimate economic and job growth in California”. Often the identified bills contain “workplace mandates” which are argued to increase labor costs.

\(^2\)The two extremes are captured in the minimum wage literature on one end (where studies commonly find either small positive or small negative elasticities) and the literature on city adjustments to shocks on the other (where, for example, Card (1990) finds virtually no wage response to the Mariel Boatlift supply shock in Miami).
estimating. The fact that the job creation curve relates wages to employment rates is important. A search and bargaining framework implies that employment rates and employment levels can react differently to wage changes and we will show that this can account for some of the heterogeneity in the finding of the labor demand elasticity literature.\(^3\)

In the canonical search and bargaining model the potential supply of job creators is assumed to be perfectly elastic - an assumption which greatly simplifies the calibration of job creation curves used in many macroeconomic models. This assumption is not innocuous, however. In most calibrated models the elasticity of job creation with respect to wages is very high precisely because of the assumption that the supply elasticity of job creator is infinite. We do not want to impose this assumption, and instead follow Fonseca, Lopez-Garcia, and Pissarides (2001) in viewing job creators as being drawn from a pool of potential entrepreneurs with different abilities. The distribution of entrepreneurial abilities in the population then becomes a factor in determining the elasticity of job creation with respect to wages. If there is an abundance of good entrepreneurs, the job creation curve will be relatively elastic. On the other hand, if good entrepreneurs are scarce and are limited by span of control problems, then the job creation curve will be relatively inelastic. Our estimation of the job creation curve with allow us to assess this issue.\(^4\)

Since we want to estimate the elasticity of job creation with respect to wages, we need to take a stance on the process of wage determination and its implications for admissible instruments. For this reason, we will also exploit properties of the second important locus in a search and bargaining model: the wage bargaining curve. This curve represents the outcome of bargaining over the match specific surplus between pairs of workers and employers. It is also a relationship between the wage and the employment rate since changes in labor market tightness alter the bargaining power of workers relative to employers. The equilibrium wage and employment rate are determined by the intersection of the job creation and wage bargaining curves. Thus, we can obtain estimates of the slope of the job creation curve if we can find exogenous shifters of the wage bargaining curve that are not directly related to the benefits of creating jobs. A substantial part of the paper is aimed at showing how and under what conditions the slope of the job creation curve can be identified with non-experimental data.

The empirical approach we use in this paper is a structural-IV approach. By this we mean that we use a structural model to carefully derive the conditions under which proposed instruments provide consistent estimates of the coefficients of interest. However, we do not directly impose the model structure on the data. Instead, we estimate relatively straightforward linear regressions using the controls and instru-

\(^3\) For example, within our search and bargaining framework a shift in labor costs (such as arises with changes in payroll taxes) can trace out the slope of the job creation curve, while a shift in the supply of available workers does not.

\(^4\) The selection mechanism for entrepreneur heterogeneity we adopt shares similarities to other work that has modeled industries as collections of heterogeneous producers (Hamermesh (1993, Chapter 4), Jovanovic (1982), Melitz (2003)). The idea that there is heterogeneity among firms has received support from the related empirical literature (see, for example, Bartelsman and Doms (2000)).
ments indicated from the theory and then test the over-identifying restrictions that are implied by the theory. Our goal is to allow the reader to fully understand the source of variation we are using to identify parameters and its relation to the theory. We depart slightly from "full" structural estimation in that we focus on estimating only first order implications of the theory as implied by its linear approximation. We believe such a choice is desirable as it offers a simple, clear and intuitive exposition of results.

Given this approach, the theory is the central building block and accordingly we begin the paper by setting out a multi-sector, multi-city version of a standard search and bargaining model. In our model, local labor markets, called cities, are linked through goods trade and labor mobility. Key to our identification strategy is an extension of the standard model to allow for multiple sectors.

Our empirical work is based on U.S. Census data from 1970-2000 and data from the American Community Survey for 2007. Our approach relies on comparing industry-city level changes in employment rates between localities with different levels of wage pressure. The differential wage pressures arise from identified shifts in the bargaining position of workers induced by predictable shifts in industrial composition. We look at effects over periods of 10 years (except for the shorter 7 year period 2000-2007), and therefore the estimates we find are associated with quite long run phenomena.

The main idea behind our identification strategy builds on an insight from Beaudry, Green, and Sand (2009, hereafter BGS) that in a search and bargaining model with multiple sectors, a shift in the sectoral composition of the workforce toward relatively high paying sectors improves the bargaining position of all workers, even holding labor market tightness constant. This arises because a worker’s outside option in bargaining with his or her employer is based on the wages the worker can obtain in alternative employment options. If, for example, a high paying steel mill closes down and is replaced by a lower paying textile mill, this affects the bargaining position of other workers in the city even if total employment has not changed. The change in bargaining positions arises because employers know that workers’ wages at their outside options are now lower and so a threat to quit carries less weight. By working with data on wages and employment rates in cells defined by city and industry, we are able to take advantage of this insight. We use the theory to show that the wage bargaining curve for an industry-city unit should shift with a change in a city-level measure of industrial composition, where movements in the composition measure reflect shifts toward or away from high paying sectors. We can then identify the slope of the job creation curve in a regression of the change in the employment rate in a city-industry cell on the change in the average wage for that cell by instrumenting for the wage using predicted changes in the industrial composition index of the city. We derive the conditions under which we can obtain two valid instruments for capturing changes in the bargaining power of workers through changes in industrial composition, and we report a clear over-identification test of the validity of the assumptions.

---

5Although labor mobility will allow expected utility to be equalized across localities, labor market frictions will nevertheless imply that wage determination maintains a local component.
The model also has other testable implications which we assess.

The main finding of the paper is that the type of labor demand specification implied by our augmented model of search and bargaining – which emphasizes employment rate-wage trade-offs – is given substantial support in the data. In particular, the specification and over-identifying restrictions implied by theory are easily accepted. Given this, we view estimates derived from this model as a reliable basis for assessing the impact of wage changes on employment outcomes. We present estimates of two types of elasticities identified by the model. At the city level, we find an estimate of $-0.3$, suggesting that the employment rate – labor cost trade-off is relatively inelastic. At the industry level, we find a larger elasticity, as predicted by the theory. We interpret the rather low city-level elasticity as partly reflecting a low propensity for individuals to become entrepreneurs and create jobs when wages are reduced. The model also provides a rationale for why studies focusing on regional adjustment yield results that seem to imply a very elastic labor demand curve. In particular, given a constant returns to scale matching technology and the assumption that potential job creators are proportional to the population, an exogenous inflow of workers simply replicates the economy, with no impacts wages or employment rates. We show that the data conforms to this property, which fits with other investigations of the nature of the matching function (Blanchard and Diamond, 1989). Expressed in wage/employment-level space this means that an inflow of workers traces out a flat relationship as employment expands with no effect on wages. Our interpretation implies that this flat relationship is not related to a perfectly elastic labor demand, but is instead a series of equilibrium points reflecting adjustments on both sides of the labor market.

The remaining sections of the paper are as follows. In section 1 we propose an extended search and bargaining model and illustrate the implications of such a model for an empirical specification of a job creation curve. In particular, we use the model to derive both an empirical specification and an instrumental variable strategy for identifying key parameters. In section 2, we present our data and discuss implementation issues. In section 3, we present our main empirical results. The model we derive implies a number of estimating strategies and we illustrate how the results from each reinforces the other by satisfying various constraints that are implied by theory. In section 4 we assess the robustness of our results. Section 5 concludes.

0.1 Related Literature

A number of stands of literature are related to this paper. First, we build on standard equilibrium search and bargaining models (Pissarides, 2000) and extend the baseline framework to include endogenous industrial composition (Acemoglu, 1999, 2001), as industrial composition pays an important role in our identification strategy. Our primary goal is to use the search and bargaining framework to see whether it can shed new light on the link between wages and employment outcomes. We are unaware of other attempts to empirically evaluate the relevance of the job creation curve and estimate its slope. In standard expositions of Mortensen-Pissarides models, researchers generally assume a perfectly elastic supply of new vacancies,
implying that the slope of the job creation curve depends solely on the rate at which vacancies are filled. Since the U.S. data indicates that vacancies are filled quickly (see for example Rogerson, Shimer, and Wright (2005)), this implies a calibration of the job creation curve which is very elastic with respect to changes in wages. However, as noted previously, we do not want to impose the assumption of a perfectly elastic supply of entrepreneurs but instead want to let the data speak. Accordingly in deriving our empirical specification of the job creation curve we follow Fonseca, Lopez-Garcia, and Pissarides (2001) in using a variant of the standard model in which heterogeneity in entrepreneurial ability allows for a potentially less than perfectly elastic supply of new vacancies. In this case the slope of the job creation curve will depend both on the speed at which vacancies are filled and on the intensity to which people will choose to become job creators as wages change.

Our paper is most closely related to work directly investigating the impact of labor costs on employment, as surveyed by Blau and Kahn (1999), and to the large literature examining local adjustment to supply shocks (see, for example, Lewis (2004), Bousstan, Fishback, and Kantor (2007) and Card (2009), among others). We depart from these studies by exporting whether a search bargaining perspective can provide a better understanding the wage-employment nexus. Our focus on long run wage effects on employment differentiates our work from studies of regional adjustment to aggregate labor demand changes (Blanchard and Katz, 1992; Bartik, 1993, 2006) which mainly focus on unemployment dynamics.

Our identification of wage effects on employment uses variation in workers’ outside options. This idea has precedents in the literature examining union wage and employment contracts (e.g., Brown and Ashenfelter (1986); MaCurdy and Pencavel (1986); Card (2009)) as these papers exploit measures of alternative wages outside the specific contract in their estimation. Card (1990) finds that the real wage in manufacturing has a positive effect on wage changes in the Canadian union contracts he studies, which echoes the mechanism underlying our basic source of identification. In a similar spirit, MaCurdy and Pencavel (1986) obtain estimates of production function parameters from data on wage and employment setting for typesetters when allowing for an alternative wage to effect the efficient outcome through an impact on union preferences.

In principle, our estimates should be easy to compare with those reported in the literature aimed at estimating the elasticity of labour demand derived within neoclassical models. Hamermesh (1993) provides the most comprehensive summary of the traditional literature estimating this elasticity. However, the question we ask is very different from the question in much of the traditional labour demand literature. We are interested in asking how employment changes when the cost of labour changes, knowing this will also affect the amount produced. In the labour demand literature the more common question is to ask how employment changes when wages

---

6 An important assumption we make regarding potential job creators is that their supply is proportional to the population. Our empirical results suggest that this proportionality assumption is a reasonable approximation.

7 Some of the concerns we have with this literature are similar to those raised in Krueger and Pischke (1997).
changes holding constant total output. In fact, in what Hamermesh calls the “long run” elasticity, these elasticities are obtained from estimates of labour demand equations with both output and the relevant wage as regressors. Such estimates provide interesting information on the elasticity of substitution between capital and labour, but they are not directly comparable with the estimates we report here. Another difference between our framework and that of the traditional labour demand literature is that labour demand literature generally use either some measure of employment or the log of employment as the dependent variable. In contrast, we argue that a search model implies that the employment rate is the relevant dependent variable and that the distinction between employment levels and employment rates is important for understanding the different results in the literature regarding how employment responds to immigration relative to how it responds to an increase in the cost of labour. Finally, the vast literature on estimating adjustment costs in a dynamic labour demand context (e.g., Bertola (1992)) is potentially relevant for our analysis given that the estimated adjustment times may be a reflection of the type of frictions that underlie search models. However the wage elasticity estimates from the dynamic labour demand literature are generally no more comparable to our estimates than those from the static demand literature.

1 Theoretical Framework

In this section, we set out an extended version of a standard search and bargaining model which incorporates multiple sectors, multiple cities, and endogenous entrepreneurial decisions. Our goal is to derive an empirical specification of the job creation curve and show how such a job creation curve can be estimated with city-level data. Because of that goal, our model is highly stylized, but we will show that it still yields strong testable implications which will allow us to evaluate whether such a simple model is a reasonable approximation of the data generating process.

We consider an economy in which there is one final good, $Y$, which is an aggregation of output from $I$ industries:

$$Y = \left( \sum_{i=1}^{I} a_i Z_i^\chi \right)^{1/\chi}, \quad \text{where } \chi < 1. \tag{1}$$

8 In Hamermesh (1993), the main estimates he reports lie in a range near -0.3, which suggest a rather low elasticity of substitution between capital and labour. While this elasticity is numerically very close to the one we obtain here, it is not appropriate to compare them as they do not address the same issue.

9 It has been pointed out to us that one could generate a specification with the employment rate as the dependent variable within a neo-classical framework if one assumes, as we do, that the number of potential entrepreneurs is proportional to the labour force and is an important factor of production. However, none of the papers directly estimating labour demand appear to have taken this approach. It is not our claim that it is impossible to derive our specification from a neoclassical model; only that the search model provides a direct rationale for the specification and implies an identification strategy and test that do not seem to us to arise naturally in other models.

10 Our model exposition shares much with that in BGS but the model in that paper emphasizes the wage bargaining curve while here we focus on the derivation of the job creation curve.
The price of the final good, $Y$, is normalized to 1 and the price of good $i$ is given by $p_i$. There are $C$ local markets, or cities, and the $i \in \{1, \ldots, I\}$ industry goods can be produced in any of these markets. The demand for the different goods is affected by the shifters $a_i$ which can be interpreted as reflecting elements of taste or technology. The industrial output in industry $i$ and city $c$, $X_{ic}$, is summed across cities to obtain the total quantity of good $i$, $\sum_c X_{ic} = Z_i$.

1.1 Search

We assume that search frictions characterize the labor markets in all cities and focus on the steady-state. For ease of presentation we will begin by assuming that workers are not mobile across cities. However, as we will see in a later section, the specification we derive here will be robust to including worker mobility and allowing expected utility to be equalized across cities.

Each local economy unfolds in continuous time and consists of firms and workers who are risk neutral, infinitely lived, and discount the future at a rate, $r$. Firms and workers come together in pairs according to a matching technology and matches end at an exogenous rate, $\delta$. Define $L_c$ as the total available number of workers in city $c$, and $E_{ic}$ and $N_{ic}$ as the number of employed workers (or matches), and the number of available jobs in industry $i$ in city $c$, respectively. Let $E_c = \sum_i E_{ic}$ and $N_c = \sum_i N_{ic}$. The number of matches produced per unit of time is governed by the matching function:

$$M = M \left((L_c - E_c), (N_c - E_c)\right),$$

where the inputs are the available pool of unemployed workers, $L_c - E_c$, and the number of vacancies, $N_c - E_c$. As is standard in the search and bargaining literature, we assume the matching technology exhibits constant returns to scale and is increasing in both arguments. We will show that the constant returns to scale assumption is validated in the empirical section.

These properties of the matching technology imply that we can write the probability that a worker encounters a vacancy and the probability a firm fills a vacancy as:

$$\psi_c = \frac{M \left((L_c - E_c), (N_c - E_c)\right)}{L_c - E_c} \quad \text{and} \quad \phi_c = \frac{M \left((L_c - E_c), (N_c - E_c)\right)}{N_c - E_c},$$

respectively. In steady state, the flow of workers leaving unemployment must equal the flow of workers exiting employment, implying the equilibrium condition:

$$\delta E_c = M \left(1 - \frac{E_c}{L_c}, \frac{N_c - E_c}{L_c}\right).$$

1.2 Bellman Equations

Firms can open jobs in any industry and city. To create a vacancy in industry $i$ in city $c$, a firm must pay a cost, $k_{ic}$, the value of which will be determined by an equilibrium free-entry condition. Denote by $V_{ic}^w$ the present-discounted value of a vacancy in
industry $i$ and city $c$. In steady-state, $V^{v}_{ic}$ must satisfy the Bellman equation:

$$rV^{v}_{ic} = -h_i + \phi_c \left(V^{f}_{ic} - V^{v}_{ic}\right), \quad (5)$$

where $h_i$ is the flow cost of maintaining the vacancy and with probability $\phi_c$ the vacancy is converted into a filled job, which has a present-discounted value of $V^{f}_{ic}$. In equilibrium, this value must satisfy

$$rV^{f}_{ic} = p_i - w_{ic} + \epsilon_{ic} + \delta \left(V^{v}_{ic} - V^{f}_{ic}\right), \quad (6)$$

where $w_{ic}$ is the wage paid to workers in industry $i$ in city $c$, and $\epsilon_{ic}$ is an industry-city cost advantage where we assume $\sum_c \epsilon_{ic} = 0$. Thus, once a match occurs, a firm enjoys a profit flow of $p_i - w_{ic} + \epsilon_{ic}$, and with probability $\delta$ the match is broken.

Workers can either be employed or unemployed. Denote the present-discounted value of employment and unemployment in industry $i$ in city $c$ as $U^e_{ic}$ and $U^u_{ic}$, respectively. The value of $U^e_{ic}$ in steady-state must satisfy the Bellman relationship:

$$rU^e_{ic} = w_{ic} + \delta \left(U^u_{ic} - U^e_{ic}\right), \quad (7)$$

When an individual is unemployed, he receives a flow utility from an unemployment benefit, $b$, plus a city-specific amenity, $\tau_c$, that can be interpreted as the difference in flow utility associated with amenities when unemployed versus when someone is employed. Let $\mu$ denote the probability that an individual is matched with his previous industry, and $1 - \mu$ the probability that he draws a job from all industries (including $i$). Thus, the value of unemployment must satisfy:

$$rU^u_{ic} = b + \tau_c + \psi_c \left(\mu \cdot U^e_{ic} + (1 - \mu) \cdot \sum_j \eta_{jic}U^e_{jc} - U^u_{ic}\right). \quad (8)$$

Embedded in (8) is the notion that as long as workers are not perfectly immobile between industries, $\mu < 1$, the utility level associated with the unemployed state depends on the utility associated with jobs across all industries. The probability of finding a job in a industry $j$ is given by $\psi_c \cdot (1 - \mu) \cdot \eta_{jic}$, where $\eta_{jic}$ denotes the share of vacant jobs in industry $j$. The implicit assumption is that the probability that a worker finds a job in another industry is proportional to the relative size of that industry.\footnote{We assume that workers only search while unemployed, which is clearly a strong assumption. This assumption is not needed to derive our empirical specification of the job creation curve but it is very useful for clarifying how we identify the wage effect on employment.}

In writing the above equations, we have assumed that there are always gains from trade between workers and firms in all jobs created in equilibrium. Once a match is made, workers and firms bargain a wage, which is set according to the bargaining rule:

$$\left(V^{f}_{ic} - V^{v}_{ic}\right) = (U^e_{ic} - U^u_{ic}) \cdot \kappa, \quad (9)$$

where $\kappa$ is a parameter governing the relative bargaining power of workers and firms.
Finally, the number of jobs created in industry $i$ in city $c$, denoted $N_{ic}$, is determined by a free entry condition for entrepreneurs. Here we follow Fonseca, Lopez-Garcia, and Pissarides (2001) and view entrepreneurs as being drawn from the population and differing in terms of their capacity to manage many jobs. In particular, we assume each individual in city $c$ (in addition to potentially being a worker) receives the option of becoming an entrepreneur in industry $i$ with probability $\tilde{\Omega}_{ic}$. There is a fixed cost, $K$, to becoming an entrepreneur. On learning of the option to be an entrepreneur, one also learns how many jobs one can manage, denoted by $n$, which is drawn from the distribution $F(n)$. Since the expected value of creating a job in industry $i$ in city $c$ is $V_{ic}^v$, all potential entrepreneurs with $n \geq \frac{K}{V_{ic}^v}$ will decide to pay the fixed cost and become an entrepreneur. Therefore, the number of jobs created in industry $i$ in city $c$ will be

$$N_{ic} = L_c \cdot \tilde{\Omega}_{ic} \cdot \int_{\frac{K}{V_{ic}^v}}^{\infty} n f(n) dn. \tag{10}$$

Note that $\tilde{\Omega}_{ic}$ can be interpreted as a city-industry comparative advantage in creating certain types of jobs. It will be convenient to decompose this advantage into two terms: $\tilde{\Omega}_{ic} = \Omega_i + \Omega_{ic}$, where $\Omega_i$ represents an industry effect that reflects systematic job creation probabilities for industries that is common to all cities, and $\Omega_{ic}$ reflects a city-industry component with the property that $\sum_c \Omega_{ic} = 0$.

Our formulation of entry decisions implies that more efficient entrepreneurs enter the market and create jobs first. In fact, Equation (10) implicitly defines the number-of-jobs-to-population ratio in an industry-city cell, $\frac{N_{ic}}{L_c}$, as an increasing function of the value of a vacancy and as an increasing function of the comparative advantage term $\Omega_{ic}$. If employment is to expand, the value of creating jobs must rise in order to maintain zero profits for the marginal entrepreneur who is of increasingly lower management capacity. This endogenous determination of entrepreneurs is an integral part of the mechanism by which changes in wages affect job creation in our model.

1.3 Model Solution

At the city level, prices of industrial goods are taken as given and an equilibrium is defined by values of $N_{ic}$, $w_{ic}$, and $\frac{E_c}{L_c}$ such that equations (4) through (10) are satisfied. At the economy-wide level, prices adjust to ensure that markets for industrial goods clear. Price changes occur when there are shifts in demand for industrial goods, captured in the model by the $a_i$ parameters. Local outcomes respond to industry prices and local advantages, captured by the $\Omega_{ic}$s and $\epsilon_{ic}$s. We will take the above description of a steady-state equilibrium as representing an equilibrium at a point in time and examine how this equilibrium changes in response to changes in the exogenous driving forces, $a_i$, $\Omega_{ic}$, and $\epsilon_{ic}$. We develop our empirical strategy by focusing on the difference between two steady-state relationships.
1.3.1 Determination of Employment

Using equations (5) and (6), we can write the value of a vacancy as:

\[ rV_{ic}^* = \alpha_{c1} \cdot h_i + \alpha_{c2} \cdot (p_i - w_{ic} + \epsilon_{ic}), \]  

(11)

where \( \alpha_{c1} = -\frac{(r+\delta)}{r+\delta+\phi_c} \) and \( \alpha_{c2} = \frac{\phi_c}{r+\delta+\phi_c} \). Note that both \( \alpha_{c1} \) and \( \alpha_{c2} \) depend on a city’s vacancy contact rates, \( \phi_c \), which, in turn, depend on the city’s employment rate, \( E_tL_t \).

It is useful to make this relationship more explicit by taking a linear approximation around the point where cities have an identical employment rate and industrial composition (this arises when cities have \( \epsilon_{ic} = 0 \) and \( \Omega_{ic} = 0 \)). In addition, to eliminate any fixed effects, it will be useful to work in log changes between two periods. We can then rewrite (11) using a log-linear approximation as:

\[ \Delta \ln V_{ict} = \tilde{\alpha}_{it} + \alpha_2 \Delta \ln w_{ict} + \alpha_3 \Delta \ln \frac{E_tL_t}{L_t} + \alpha_4 \Delta \epsilon_{ict}, \]  

(12)

where \( \Delta x_{it} = x_{it} - x_{it-1} \) and we have added time subscripts because we will use data from several periods. The \( \tilde{\alpha}_{it} \)s correspond to industry-year specific effects, and, hence, can be captured in an empirical specification by industry-year dummy variables. The coefficients \( \alpha_2 \) and \( \alpha_3 \) (which are evaluated at common vacancy filling rates) are predicted to be negative since, all else equal, the return to opening new jobs will be lower when wages are higher and when the labor market is tighter (implying a longer time to fill a vacancy). The last term is an error term that depends on the city-industry cost advantages.

We now want to relate the change in the value of a vacancy to the employment rate in an industry. To do this, we first log-linearize (10) and, taking differences between two periods, we arrive at:

\[ \Delta \ln \frac{N_{ict}}{L_t} = \theta_1 \Delta V_{ict}^* + \theta_2 \Delta \Omega_{ict}, \]  

(13)

where \( \theta_1 \) is positive since as the value of vacancies increase the incentive to create jobs increases. By replacing \( \Delta V_{ict}^* \) in 13 with its expression given in 12, we can obtain an expression for job creation in an industry city cell as a function of wages and overall labor market tightness. As we wish to get an expression in terms employment instead of jobs, we use the fact that \( \delta \cdot E_{ic} = \phi_c \cdot [N_{ic} - E_{ic}] \) \( \forall i \). Using this last expression in conjunction with 13 and 12 give us the main expression determining employment:

\[ \Delta \ln \frac{E_tL_t}{L_t} = \varphi_{it} + \varphi_2 \Delta \ln w_{ict} + \varphi_3 \Delta \ln \frac{E_tL_t}{L_t} + \zeta_{ict}, \]  

(14)

where the \( \varphi_{it} \) represent a set of common industry-year effects, and \( \varphi_2 \) is the elasticity of industry employment creation with respect to wages holding the aggregate employment rate constant. Note that this elasticity is increasing in \( \theta_1 \). This arises because a high value of \( \theta_1 \) means that the density function of management capacity is such that many jobs are created in response to a fall in wages. Hence, in this model, one of the reasons that the elasticity of employment with respect to wages can be low is that the supply of entrepreneurial activity may have a low elasticity with respect
to variable profits. The more common assumption in the search and bargaining literature is that the cost of creating jobs is constant (often zero) implying that – holding aggregate tightness constant – job creation should be infinitely elastic. By estimating equation (14) we will be able to examine whether this assumption is appropriate.

The coefficient, $\varphi_3$ in (14) is predicted to be negative because a tighter labor market increases the duration of vacancies, thereby lowering the return to opening a vacancy in any sector. Thus, $\varphi_3$ captures classic congestion externalities in a search model extended to include multiple sectors. The implication that city-level changes in the employment rate have a negative effect on employment rates within industries is somewhat counterintuitive in the absence of the model and, as a result, can be seen as an interesting testable implication of the model. This is especially the case when one notes that changes in wages are held constant in (14): increased demand in sector A could induce reductions in employment in sector B in a standard demand and supply model, but that effect would operate through wage changes. The last term in (14), $\zeta_{ic} = \frac{1}{\beta_1} (\alpha_4 \Delta \epsilon_{ic} - \theta_2 \Delta \Omega_{ic})$, is an error term that depends on city variable costs and job creation advantages.

Equation (14) forms the basis of our empirical investigation and can be interpreted as a job creation curve at the city-industry level. Notice that the equation involves a reflection problem (Manski, 1993; Moffitt, 2001). To see this, note that $\Delta \ln \frac{E_{ic}}{L_{ic}}$ can be approximated by $\sum_i \eta_{ict} \Delta \ln \frac{E_{ic}}{L_{ic}}$ so that (14) involves a regression of the change in the log employment rate in a given city-industry cell, $\Delta \ln \frac{E_{ic}}{L_{ic}}$, on its average across such cells within a city. We could address this issue directly via an instrument or solve out for $\Delta \ln \frac{E_{ic}}{L_{ic}}$. We implement both approaches in our empirical work. However, this will not solve all of the simultaneity problems inherent in (14), since within-industry wage changes, $\Delta \ln w_{ic}$, are simultaneously determined with $\Delta \ln \frac{E_{ic}}{L_{ic}}$ in the model and, as we show in the following section, are also a function of the city-wide employment rate. Thus, to consistently estimate (14), we must identify variation in wages that is uncorrelated with $\Delta \epsilon_{ic}$ and $\Delta \Omega_{ic}$ in the error term in (14) and that is separate from variation in the city employment rate. The following section discusses the relevant aspects of the wage determination process in a search and bargaining framework which can be used to deal with the simultaneity issues.

### 1.3.2 Determination of Wages

In order to get an expression for wages, we begin with equations (5) and (6) in order to derive an expression for $V^f_{ic} - V^v_{ic}$. Similarly, equations (7) and (8) can be used to derive an expression for $U^e_{ic} - U^w_{ic}$. Using these expressions along with the bargaining equation (9), we can write the following wage equation:

$$w_{ic} = \gamma_{c0} + \gamma_{c1} p_i + \gamma_{c2} \sum_j \eta_{jc} w_{jc} + \gamma_{c1} \epsilon_{ic}. \quad (15)$$

---

**Note:** This section is a much shortened version of the discussion in BGS. Thus, BGS can be seen as an extended investigation of the first-stage in the estimation of the job creation curve in this paper.
Equation (15) links wages in industry $i$ in city $c$ to the national price of the industrial good, $p_i$, and the average level of wages in city $c$.\(^{13}\) Equation (15) captures the notion that, in a multi-sector search and bargaining model, sectoral wages act as strategic complements; that is, within a city, high wages in one sector are associated with high wages in other sectors. This follows directly from a combination of equations (7) and (8), which show that a worker’s outside option in bargaining depends on the wages he could get at other jobs in the city, weighted by the probabilities of getting those jobs. The intercept, $\gamma_{c0}$, is a function of unemployment benefits, $b$. Thus, (15) reflects the standard search model result that wages are a function of productivity ($p_i + \epsilon_{ic}$) and the value of a worker’s outside option (which is, in turn, a function of $b$ and the wage he would expect to earn in other sectors in the city).

The wage equation, (15), again contains a classic reflection problem in that the wage differential, we can rewrite the wage equation (15) as a function of national-level wage premia. In particular, through a series of simple derivations, we can rewrite the wage equation (15) as

$$w_{ic} = \hat{d}_{ic} + \left(\frac{\gamma_2}{1 - \gamma_2}\right) \left(\frac{\gamma_1 c_1}{1 - \gamma_1 c_1}\right) \sum_j \eta_{jc} \nu_j + \gamma_{c1} \epsilon_{ic} + \gamma_{c1} \left(\frac{\gamma_2}{1 - \gamma_2}\right) \sum_j \eta_{jc} \epsilon_{jc}, \quad (16)$$

where, $\nu_i = w_i - w_1$ (the wage premium relative to an arbitrary baseline industry, 1, at the national level), and $\hat{d}_{ic}$ is a function of $\gamma_{c0}, \gamma_{c1}, \gamma_{c2}$ from equation (15) as well as of $p_i$. We refer the reader to BGS for the derivation linking (15) to (16), but note that the $\gamma$ coefficients are functions of $\phi_c$ and, therefore, of the city-level employment rate.

Equation (16) states that wages within an industry-city cell depend on the industrial composition of a city as captured by the index $\sum_j \eta_{jc}(w_i - w_1)$. We will denote this index by $R_c$ and refer to it as average city rent. A high value of this index indicates that a city’s employment is concentrated in high paying industries. Thus, the specific composition effect captured in (16) is one related to the proportion of “good jobs” in a city, where by good jobs we mean jobs in industries that pay a relative wage premium.\(^{14}\)

As with the job creation curve, it is useful to make the dependence of wages on the city’s employment rate more explicit by taking a linear approximation of (16) under the same conditions that were used to derive equation (11). Furthermore, to eliminate the city-level fixed effects driven by the amenity, $\tau_c$, we focus on the difference in wages within a city-industry cell across two steady state equilibria, denoted $\Delta w_{ic}$. This is given by equation (17):

$$\Delta w_{ic} = \Delta d_i + \left(\frac{\gamma_2}{1 - \gamma_2}\right) \sum_j \eta_{jc} \nu_i + \gamma_5 \frac{E_c}{L_c} + \Delta \xi_{ic}, \quad (17)$$

\(^{13}\)Recall that $\eta_{jc}$ is the share of employment in industry $j$ in city $c$. The coefficients in (15) are $\gamma_{c0} = \frac{1}{(r^h + \delta + \psi_c, \mu)(r^h + \delta + \psi_c, \kappa)(r^h + \delta + \psi_c)} (b + \tau_c)$, $\gamma_{c1} = \frac{r^h + \delta + \psi_c, \mu}{(r^h + \delta + \psi_c, \mu)(r^h + \delta + \psi_c, \kappa)(r^h + \delta + \psi_c)}$ and $\gamma_{c2} = \frac{(r^h + \delta + \psi_c, \kappa)}{(r^h + \delta + \psi_c, \mu)(r^h + \delta + \psi_c, \kappa)(r^h + \delta + \psi_c)} \psi_c (1 - \mu)$. See BGS for additional details on deriving this expression.

\(^{14}\)It is important that these wage differentials are rents – if they just reflect compensating differentials or industry-specific skills then workers in other industries could not use them as the basis for bargaining for a better wage.
where $\Delta d_i$ is an industry-specific effect incorporating $\Delta p_i$ which can be captured by industry dummy variables in our empirical specification; and $\Delta \xi_{ict} = \gamma_1 \Delta \epsilon_{ict} + \gamma_1 \frac{\eta_{ict}}{\nu_{ict}} \sum_j \frac{1}{\gamma_2} \Delta \epsilon_{jc}$ is the error term. The coefficient $\gamma_1$ is implied by the theory to be positive as it reflects the effect of labor market tightness on wages.

To obtain our final equation for wages, we divide both sides of (17) by $w_1$ in order to focus on a log specification and re-introduce time subscripts since we will pull data from different periods:

$$\Delta \ln w_{ict} = d_{it} + \beta_2 \Delta R_{ct} + \beta_3 \Delta \ln E_{ict} + \Delta \xi_{ict},$$

where the $d_{it}$s are time-varying industry effects, $\beta_2 = \frac{\gamma_2}{1-\gamma_2}$ gives the impact of a change in industrial composition on wages, $R_{ct} = \sum_i \eta_{ic} \left( \frac{w_i}{w_1} - 1 \right)$ is our index of industrial composition, $\beta_3 = \frac{\gamma_5}{w_1}$ is the coefficient capturing the effect of city-level employment rates on wages, and $\Delta \xi_{ict}$ is the error term defined by $\Delta \xi_{ict} = \frac{\gamma_1}{w_1} \Delta \epsilon_{ict} + \frac{\gamma_1}{w_1} \frac{\gamma_2}{1-\gamma_2} \sum_j \frac{1}{\gamma} \Delta \epsilon_{jc}$.

### 1.4 Dealing with Endogeneity

The wage equation (18) developed in the previous section highlights the difficulties in identifying the parameters in the job creation equation (14). In particular, with $\Delta \ln w_{ict}$ on the right hand side of (14) and local productivity shocks (the $\epsilon_{ict}$s) appearing in the error terms for both $\Delta \ln w_{ict}$ and $\Delta \ln E_{ict}$, we face a standard endogeneity problem. At first glance, the derivation of the wage and job creation equations in a multi-sector context also suggests a potential instrument: $\Delta R_{ct}$, the change in industrial composition, affects $\Delta \ln w_{ict}$ through its impact on bargaining positions but affects $\Delta \ln E_{ict}$ only indirectly, through its impact on wages. As described earlier, estimating equation (14) also involves solving a reflection problem. We return to that problem below.

While $\Delta R_{ct}$ may appear at first to be a good candidate for an instrument, there are reasons to question its validity. To see this, consider a standard decomposition of $\Delta R_{ct}$ given by,

$$\Delta R_{ct} = \sum_i (\eta_{ict} - \eta_{ict-1}) \cdot \nu_{it-1} + \sum_i \eta_{ict} \cdot (\nu_{it} - \nu_{it-1}).$$

It is straightforward to show that the $\eta$s (the industry shares) can be written as functions of the $\epsilon$s and $\Omega$s (the local productivity shocks and cost advantages). Since $\Delta \epsilon$s and $\Delta \Omega$s are present in the error term of equation (14), this implies that $\Delta R_{ct}$ is also likely correlated with the error term in our employment rate equation.

Our approach is to construct instruments that are related to $\Delta R_{ct}$ using what is sometimes called a shift-share IV approach. This approach was developed in Bartik (1993) and has been used in a long list of papers, including, most notably, Blanchard and Katz (1992). The idea is to break the link between $\Delta \eta_{ict}$ in the first component of $\Delta R_{ct}$ and the error term by using predicted values of $\Delta \eta_{ict}$ based on national...
industry-level growth rates. In particular, we first predict the level of employment for industry $i$ in city $c$ in period $t$ as:

$$\hat{E}_{ict} = E_{ict-1} \left( \frac{E_{it}}{E_{it-1}} \right).$$

Thus, we predict period $t$ employment in industry $i$ in city $c$ using the employment in that industry-city cell in period $t-1$ multiplied by the national-level growth rate for the industry. We then use these predicted values to construct predicted industry-specific employment shares, $\hat{\eta}_{ict} = \frac{\hat{E}_{ict}}{\sum_i \hat{E}_{ict}}$, for the city in period $t$ and, finally, form our first instrument as:

$$IV_{1ct} = \sum_i \nu_{it-1} \cdot (\hat{\eta}_{ict} - \eta_{ict-1}) = \sum_i \eta_{ict-1} \cdot (g^*_it - 1) \cdot \nu_{it-1},$$

(20)

where $g^*_it = \frac{1+g_{it}}{\sum_k \eta_{ikt}(1+g_{kt})}$ and $g_{it}$ is the growth rate in employment in industry $i$ at the national level. This instrument is closely related to the first component of the decomposition of $\Delta R_{ct}$: the component relating just to changes in the employment composition. The idea underlying this instrument is that we are using national-level changes to predict where bargaining power for workers will be most affected (specifically, in cities concentrated in declining, high-paying industries). According to the model, in such cities, wages should decrease and the employment rate within industries should increase.

To understand the conditions under which this instrument would provide consistent estimates of the parameters in (14) (apart from it being strongly correlated with the change in wages, which we will demonstrate), re-state $\epsilon_{ict}$ (and $\Omega_{ict}$, as well) as the sum of a common city component (or absolute advantage component) and a second, relative advantage component. Thus, denote $\bar{\epsilon}_{ct}$ and $\bar{\Omega}_{ct}$ as the common components of the $\epsilon$s and the $\Omega$s, respectively, and let $v^\epsilon_{ict}$ and $v^\Omega_{ict}$ represent the relative advantage components. Then, $\epsilon_{ict} \equiv \bar{\epsilon}_{ct} + v^\epsilon_{ict}$ and, by definition, the $v^\epsilon_{ict}$s across industries within a city sum to zero (with a similar expression for $\Omega_{ict}$).

Intuitively, inspection of (20) reveals that variation in $IV_{1ct}$ stems from differences in industry shares across cities (weighted by national-level industrial growth rates and wage premia. Since $IV_{1ct}$ varies only at the city level, having it be uncorrelated with the error term in (14), $\zeta_{ict} = \frac{1}{a_{it}} (\alpha_4 \Delta \epsilon_{ict} - \theta_2 \Delta \Omega_{ict})$, requires that the start of period industrial composition for a city is uncorrelated with average productivity ($\Delta \bar{\epsilon}_{ct}$) and cost ($\Delta \bar{\Omega}_{ct}$) changes. This makes intuitive sense since it implies that our instrument is reflecting changes related to industrial composition (which we have argued shifts the wage bargaining curve) but not general changes in productivity in the city (which would also shift the job creation curve - the very curve we are trying to identify). In terms of the fundamental elements of the model, one can show that $\eta_{ict-1}$ can be written solely as a function of the relative advantage components, $v^\epsilon_{ict}$ and $v^\Omega_{ict}$ (see Appendix A for details). Thus, the identifying assumption for $IV_{1ct}$ is $\text{cov}(v^\epsilon_{ict}, \Delta \bar{\epsilon}_{ct}) = \text{cov}(v^\epsilon_{ict}, \Delta \bar{\Omega}_{ct}) = \text{cov}(v^\Omega_{ict}, \Delta \bar{\epsilon}_{ct}) = \text{cov}(v^\Omega_{ict}, \Delta \bar{\Omega}_{ct}) = 0$.

Extra intuition for our identifying strategy can be seen from sketching out the proof of the consistency conditions for $IV_{1ct}$ under the identifying assumption just
specified (see Appendix A for complete details). In particular, we require,

$$\lim_{C,I \to \infty} \frac{1}{I C} \sum_{i=1}^{I} \sum_{c=1}^{C} IV1_{ct} \zeta_{ict} = \lim_{C,I \to \infty} \frac{1}{I C} \sum_{c=1}^{C} IV1_{ct} \sum_{i=1}^{I} \zeta_{ict} = 0,$$

or,

$$\lim_{C,I \to \infty} \frac{1}{I C} \sum_{c=1}^{C} \left( \sum_{j} \eta_{jct-1} \cdot (g_{jt}^* - 1) \cdot \nu_{jt}\right) \sum_{i} \zeta_{ict} =$$

$$= \lim_{C,I \to \infty} \frac{1}{I C} \sum_{j} (g_{jt}^* - 1) \cdot \nu_{jt} \left[ \sum_{c} \eta_{jct-1} \cdot \sum_{i} \zeta_{ict} \right]$$

$$= \lim_{I \to \infty} \frac{1}{I} \sum_{j} (g_{jt}^* - 1) \cdot \nu_{jt} \lim_{C \to \infty} \frac{1}{C} \left[ \sum_{c} \eta_{jct-1} \cdot \sum_{i} \zeta_{ict} \right]$$

$$= 0,$$  \hspace{1cm} (21)

Let us focus on the last term in the above derivation. If we consider the limit $C \to \infty$ first, then we are only concerned with the term in the bracket $\left[\right]$. As we stated earlier, $\eta_{jct-1}$ is a function only of $v_{ict}$ and $\nu_{ict}$, while $\sum_{i} \zeta_{ict}$ will only be a function of $(\Delta \bar{\epsilon}_{ct})$ and cost $(\Delta \bar{\Omega}_{ct})$ since summing across industries will eliminate changes in the relative advantage components of $\Delta \epsilon_{ict}$ and $\Delta \Omega_{ict}$. Thus, it can be seen that the limit in (21) equals zero if the vectors $(v_{ict}, \nu_{ict})$ and $(\Delta \bar{\epsilon}_{ct}, \Delta \bar{\Omega}_{ct})$ are uncorrelated.

Sketching out the proof is helpful for clarifying a potentially confusing point. Because national-level industrial growth rates ($g_{it}$) are aggregates of city-level growth and, therefore, of city-level productivity, one might be concerned that the presence of $g_{jt}^*$ in $IV1$ creates a problematic correlation with the error term. But the expression in (21) makes it clear this is not the case. The reason is that (with the inclusion of a complete set of industry and time dummies) our identifying variation is cross-city, within-industry variation. That is, using $IV1$, we are comparing employment rate changes in an industry between cities predicted to have more versus less growth in what we have called average rent. The changes in predicted rent are based partly on national-level growth rates, but those are the same for all cities and so do not introduce problematic variation. In terms of the proof, this can be seen from the fact that the $g_{jt}^*$ and $\nu_{jt}$ terms are pulled outside the city-level summation and so are irrelevant for the consistency condition. This property will also apply to the other instruments we use which have a similar shift-share structure.\(^{16}\)

The key random walk-type assumption that we require for identification may or may not seem intuitively defensible. In this situation, over-identification restrictions can play a crucial role in allowing us to check on the assumptions. In our case, the decomposition of $\Delta R$ in (19) suggests a second instrument that is based on the second decomposition component:

$$IV2_{ct} = \sum_{i} \hat{\eta}_{ict} \cdot (\nu_{it} - \nu_{it-1}).$$  \hspace{1cm} (22)

\(^{16}\text{The type of instrument we use here is rather common in the labour literature. However we are not aware of any other formal discussion of when and under what conditions it is an appropriate instrument.}\)
The main point for our purposes is that $IV_2$ again takes the form of start-of-period industry-city shares multiplying national-level industrial premia and growth rates. As with $IV_1$, the national-level variables are not relevant for the consistency condition proof and so consistency again depends on the same assumptions as for $IV_1$. Importantly, though, if the assumptions are violated (and $\eta_{ict} - 1$ is correlated with $\Delta \tilde{\epsilon}_{ct}$ or $\Delta \tilde{\Omega}_{ct}$), the resulting non-zero correlation will be weighted by different functions of national-level entities for $IV_1$ versus $IV_2$. Thus, if the key assumptions are violated, the biases should be different when using $IV_1$ versus $IV_2$ and we would reject the null hypothesis that model is correct in a standard over-identification test.

The over-identification test based on $IV_{1,ct}$ and $IV_{2,ct}$ is, at the same time, a test of the model. The two instruments represent substantially different forms of variation, with one based on movements in national-level employment growth and the other on movements in national-level wage premia. In fact, in our Census data, described in section 2, their correlation (after removing year effects as we do in all of our estimations), is only 0.18. Yet, the model indicates that both types of variation should have the same effect on wages and, through them, on employment rates since what matters for a worker's bargaining position is the change in the average wage in other industries, regardless of whether that change stems from changes in industrial composition or the industrial wage premia. Thus, a standard over-identification test represents a strong test of the model together with the assumptions under which the instruments are valid. As with all such tests, it is not impossible that an alternative model would imply the same test statistic but we have not been able to discern what such a model would look like, while the restriction is a clear implication of a search and bargaining model.

### 1.4.1 Endogeneity of Employment Rates

The last endogeneity issue relates to the potential correlation between the change in the employment rate, $\Delta \ln \frac{E_c}{L_c}$, and the error term in (14) arising from the fact that $\Delta \ln \frac{E_c}{L_c}$ is an aggregation of the dependent variable in (14). Our first response that problem is to use an instrument that is similar to $IV_1$ and similar to the one used in Blanchard and Katz 1992. In particular, we use as an instrument $\sum_i \eta_{ict} - 1 \cdot g_{it}$, where $g_{it}$ is the growth rate of employment in industry $i$ at the national level. We will refer to this instrument as IV3. This instrument is the weighted average of national-level industrial employment growth rates, where the weights are the start of period industrial employment shares in the local economy. A city that has a strong weight on an industry that turns out to grow well at the national level will have a high value for this instrument. The $\epsilon_{ic}$s and the $\Omega_{ic}$s that make up the error term of our estimating equation are local shocks that sum to zero across cities. Therefore, their movements are not correlated with the $g_{it}$s by construction. Finally, under the assumption that innovations in the absolute components of the local shocks, $\Delta \tilde{\epsilon}_{ct}$ and $\Delta \tilde{\Omega}_{ct}$, are independent of past relative advantage components, $v^r_{ict}$ and $v^\Omega_{ict}$, the changes in $\epsilon_{ict}$ and $\Omega_{ic}$ that constitute $\sum_i \zeta_{ict}$ will be independent of the $\eta_{ict} - 1$ used as weights in the instrument. Therefore, this instrument is valid under the same conditions as $IV_1$ and $IV_2$. We can also respond to the reflection problem inherent
in (14) by forming a consistent expression for $\Delta \ln \frac{E_{ct}}{L_{ct}}$ as a function of other variables in the model and substituting it in for $\Delta \ln \frac{E_{ct}}{L_{ct}}$. We will also pursue that approach in section (3).

1.5 Addressing the Reflection Problem: Second Method

In the previous subsections, we proposed addressing the reflection problem relating to city-wide employment rates via instrumental variables. The alternative, which we describe here, is to substitute out for the city-wide employment rates. In particular, aggregating over industries, we can re-write (14) as:

$$
\Delta \ln \frac{E_{ct}}{L_{ct}} = \sum_i \eta_{ict-1} \cdot \frac{\varphi_{it}}{1 - \varphi_3} + \sum_i \eta_{ict-1} \cdot \frac{\varphi_2}{1 - \varphi_3} \Delta \ln w_{ict} + \sum_i \eta_{ict-1} \cdot \frac{\zeta_{ict}}{1 - \varphi_3}.
$$

(23)

Noticing that $\varphi_{it}$ relates to national-level industry growth rates, it can be shown that $\sum_i \eta_{ict-1} \cdot g_{it}$ can be translated into a set of year dummies and the term $\sum_i \eta_{ict-1} \cdot g_{it} - \varphi_2 \sum_i \eta_{ict} \cdot \Delta w_{it}$, where $g_{it}$ is the growth rate of employment in industry $i$ at the national level and $\Delta w_{it}$ is the growth in the average (across cities) log wage. Hence, we can write a specification that aggregates over industries as:

$$
\Delta \ln \frac{E_{ct}}{L_{ct}} = d_t + \frac{1}{1 - \varphi_3} \cdot \sum_i \eta_{ict-1} \cdot g_{ct} + \frac{\varphi_2}{1 - \varphi_3} \cdot \sum_i \eta_{ict-1} \left( \Delta \ln w_{ict} - \Delta w_{it} \right) + \tilde{\zeta}_{ct},
$$

(24)

where $d_t$ represent year fixed effects and $\tilde{\zeta}_{ct}$ is an error term. The variable $\sum_i \eta_{ict-1} \cdot g_{it}$ is city-level predicted employment growth and is the same variable we used to instrument $\Delta \ln \frac{E_{ct}}{L_{ct}}$ in the industry-city level equations. Under our maintained assumption, it is uncorrelated with the error term. Notice that the model implies that its coefficient, $\frac{1}{1 - \varphi_3}$, should be positive: cities with a high initial concentration in industries that grow well at the national level have a greater increase in their city level employment ratio. Since $\tilde{\zeta}_{ct}$ is essentially an aggregation of $\zeta_{ict}$, estimation of (24) involves the same endogeneity problems related to the wage variable as (14) and instrumental variables estimation using $IV_1$ and $IV_2$ provide consistent estimates of

---

17. In performing this aggregation, we have made use of the approximation $\sum_i \eta_{ict-1} \Delta \ln \frac{E_{ct}}{L_{ct}} \approx \Delta \ln \frac{E_{ct}}{L_{ct}}$.

18. To see this, rewrite (14) as

$$
\Delta \ln \frac{E_{ct}}{L_{ct}} = \varphi_{it} + \varphi_2 \Delta \ln w_{ict} + \varphi_3 \cdot \Delta \ln E_{ct} + (1 - \varphi_3) \cdot \Delta \ln L_{ct} + \zeta_{ict}.
$$

Taking the sum of this equation over cities using the weights $\omega_c = \frac{E_{ct}}{\sum_c E_{ct}}$, where 0 denotes the initial year, gives:

$$
\sum_c \omega_c \Delta \ln \frac{E_{ict}}{L_{ict}} = \varphi_{it} + \varphi_2 \sum_c \omega_c \Delta \ln w_{ict} + \varphi_3 \cdot \sum_c \omega_c \Delta \ln E_{ict} + (1 - \varphi_3) \cdot \sum_c \omega_c \Delta \ln L_{ict} + \sum_c \omega_c \zeta_{ict}.
$$

This implies that $\varphi_{it}$ can be written as $\varphi_{it} = \sum_c \omega_c \Delta \ln E_{ict} - \varphi_2 \sum_c \omega_c \Delta \ln w_{ict} + d_t - \sum_c \omega_c \zeta_{ict}$, where $d_t$ is a year fixed effect. Now taking the sum over $i$: $\sum_i \eta_{ict} \varphi_{it} = \sum_i \eta_{ict} \varphi_{it} - \varphi_2 \sum_i \eta_{ict} \cdot \Delta \ln w_{ict} + d_t - \sum_i \eta_{ict} \sum_c \omega_c \zeta_{ict}$, where $\Delta w_{ict}$ is the growth in the average (across cities) log wage. Since, by assumption, $\sum_c \zeta_{ict} = 0$, the last term behaves approximately like white noise. The term $d_t$ varies only by year and can be captured in an empirical specification by year dummies.

19. In deriving equation (24), we have again made use of the approximation $\sum_i \eta_{ict-1} \cdot \Delta \ln \frac{E_{ct}}{L_{ct}} \approx \Delta \ln \frac{E_{ct}}{L_{ct}}$. 

17
the coefficients under the same assumptions as in our earlier specification. Also as in the disaggregated specification, the model and identifying assumptions together imply a strong over-identification test in the sense that \( IV_1 \) and \( IV_2 \) should identify the same coefficients in spite of being only weakly correlated with each other.

Through aggregation and rearranging, specification (24) no longer has changes in the employment rate at different levels of aggregation on each side of the regression. This eliminates the reflection problem. At the same time, the coefficient on the wage variable on the right hand side becomes \( \frac{\varphi_2}{1-\varphi_3} \), which is the city-level labor demand elasticity. To see this, recall that \( \varphi_2 \) is the coefficient on the wage variable in the disaggregated specification (14) and corresponds to the labor demand elasticity at the industry-city level. Since all industries will adjust employment downward in response to a general wage increase, there will be feedback effects on overall employment rates and the city-level elasticity, which, allowing these equilibrium effects to play out, will be \( \frac{\varphi_2}{1-\varphi_3} \). Since we obtain direct estimates of \( \varphi_2 \) and \( \varphi_3 \) from implementing (14), we will obtain estimates of the city-level elasticity both directly from (24) and indirectly from (14). These specifications use very different levels of variation and we view a finding of similar estimates from these different specifications as another test of the implications of the model.

### 1.6 Worker Heterogeneity

As we have indicated, our aim in this paper is to provide an estimate of how employment, on average, is affected by an across-the-board increase in the cost of labor. By its very nature, this question is about an aggregate labor market outcome. In the model developed so far all workers are identical and so all parameters are “aggregate” by definition. However, in our data, workers are heterogeneous in, for example, education and experience. We need to address this heterogeneity in order to provide a consistent answer to our aggregate question. Depending on the assumptions that one makes, there are several ways to approach this issue.

Our first approach, which we use for our main set of results, is to treat individuals as representing different bundles of efficiency units of work, where these bundles are treated as perfect substitutes in production. Therefore, we control for skill differences in wages via a regression adjustment. However, the theory indicates that we should not account for differences in worker attributes when aggregating the number of workers across industries and cities in the calculation of employment rates. In Appendix C, we present a formal justification for such an approach. Heuristically, the structure of the basic search model allows one to write the wage of any skill type in units of some arbitrary type, which rationalizes the use of the regression adjusted wages. In addition, random matching implies that the probability of meeting a worker of a given skill type will equal the product of the vacancy filling rate and the proportion of that worker’s type in the local economy. Thus, the effects of labor market tightness and skill can be separated and, we argue in the appendix, that the latter effects can be expected to be relatively small. Hence, the value of a vacancy will depend on the skill distribution of the workforce in general, but it is probably only of second-order importance. Our approach is to ignore these additional effects
in our baseline specification. However, in the robustness section we will show that
our results are not sensitive to controlling for measures of the aggregate distribution
of skill in a locality.

An alternative assumption is that labor markets are segregated along observ-
able skill dimensions and that our model applies to homogeneous workers within
these markets. Thus, we also perform our analysis separately by education group
as a specification check. Finally, if one assumes that the matching function is not
over workers but over efficiency units then it is appropriate when aggregating work-
ers over industries and cities to use efficiency weighted worker counts. When we
construct our employment variables in this manner it does not substantially affect
our main results. However, we choose not to pursue this interpretation as it appears
quite artificial in the search bargaining context. Nonetheless, results using efficiency
units are available by request.

1.7 Mobility

The model presented above assumes that workers are not mobile across localities. It
may seem, at first, that allowing for worker mobility could overturn the result that
wages differ across localities because of local bargaining conditions. However, even
when we allow for directed search across cities, wage differentials between cities will
generally continue to persist. In Appendix D, we offer two extensions of the model
that take into account worker mobility. In the first extension, unemployed workers
are not perfectly mobile, but are only occasionally offered the opportunity to switch
cities. Because of this friction, wages (and outside options) will maintain a local
component. When the option to switch cities arises, workers choose the city that
maximizes the value of their search. Since this choice will not depend on the initial
location of the worker, it acts as a common element across workers and is captured
by an intercept. In this extension of the model, none of our empirical specifications
are affected and the model’s implications will continue to hold.

In the second extension, we go further by modeling more explicitly the spatial
equilibrium. In particular, we introduce local housing prices and allow workers to
choose a city that maximizes expected utility, taking into account housing costs and
local amenities. In this extension, we modify workers’ Bellman equations, (8) and (7),
to include a negative function of the local housing price. Importantly, housing prices
will not directly affect wage negotiation because it is a cost that is incurred whether
or not an individual is employed (and wages depend on the difference $U_{ic}^e - U_{ic}^u$).
However, housing prices will have to adjust to equilibrate expected utility across
cities. In Appendix D, we present this simple model with housing costs that depend
positively on local amenities and city size. We show that it implies that a city with
a higher employment rate or a higher expected wages (i.e., due to higher values of
$R_{ct}$) will attract more workers. This in-migration will drive up local housing costs
to the point where expected utility is equalized across cities, but in-migration will
stop before wage equalization occurs. Thus, the forces we emphasize in our model

---

20 Random search across cities has the same implication.
also have implications for worker mobility and housing costs. Toward the end of the paper, we present results which support this mechanism.

2 Data Description and Implementation Issues

The data we use in this paper come from the U.S. decennial Censuses from the years 1970 to 2000 and from the American Community Survey (ACS) for 2007. For the 1970 Census data, we use both metro sample Forms 1 and 2 and adjust the weights for the fact that we combine two samples. We focus on individuals residing in one of our 152 metropolitan areas at the time of the Census. Census definitions of metropolitan areas are not comparable over time. The definition of cities that we use in this paper attempts to maximize geographic consistency across Census years. Since most of our analysis takes place at the city-industry level, we also require a consistent definition of industry affiliation. Details on how we construct the industry and city definitions are left to Appendix B.

As discussed earlier, our approach to dealing with worker heterogeneity is to control for observed characteristics in a regression context. Since most of our analysis takes place at the city-industry level, we use a common two-step procedure. Specifically, using a national sample of individuals, we run regressions separately by year of log weekly wages on a vector of individual characteristics and a full set of city-by-industry dummy variables. We then take the estimated coefficients on the city-by-industry dummies as our measure of city-industry average wages, eliminating all cells with fewer than 20 observations.

Our interpretation of the regression adjusted wage measure is that it represents the wage paid to workers for a fixed set of skills. However, since we only observe the wage of a worker in city \( j \) if that worker chooses to live and work in \( j \), self-selection of workers across cities may imply that average city wages are correlated with unobserved worker characteristics such as ability. In this case, our wage measure will not represent the wage paid per efficiency unit but will also reflect (unobservable) skill differences of workers across cities. To address this potential concern, when we estimate our wage equations we control for worker self-selection across cities with a procedure developed and implemented by Dahl (2002) in a closely related context.

Dahl proposes a two-step procedure in which one first estimates various location choice probabilities for individuals, given their characteristics such as birth state. In the second step, flexible functions of the estimated probabilities are included in the wage equation to control for the non-random location choice of workers.

\(^{21}\)Our data was extracted from IPUMS, see Ruggles, Sobek, Alexander, Fitch, Goeken, Hall, King, and Ronnander (2004)

\(^{22}\)We take a flexible approach to specifying the first-stage regression. We include indicators for education (4 categories), a quadratic in experience, interactions of the experience and education variables, a gender dummy, black, hispanic and immigrant dummy variables, and the complete set of interactions of the gender, race and immigrant dummies with all the education and experience variables.

\(^{23}\)Since the number of cities is large, adding the selection probability for each choice is not practical. Therefore, Dahl (2002) suggests an index sufficiency assumption that allows for the inclusion of a smaller number of selection terms, such as the first-best or observed choice and the retention probability. This is
actual procedure that we use is an extension of Dahl’s approach to account for the fact we are concerned with cities rather than states, as in his paper, and that we also include individuals who are foreign born. When we estimate the wage equations, the selection correction terms enter significantly, which suggests that there are selection effects. Our results with or without the Dahl procedure are very similar. Nevertheless, all estimates presented below include the selection corrected wages.\footnote{Details on our implementation of the Dahl’s procedure are contained in Appendix E. Results without the selection correction are very similar to those reported here, and are available upon request.}

One of our main covariates of interest is the $\Delta R_{ct}$ variable which is a function of the national-industrial wage premia and the proportion of workers in each industry in a city. We estimate the wage premia in a regression at the national level in which we control for the same set of individual characteristics described for our first-stage wage regression and also include a full set of industry dummy variables. This regression is estimated separately for each Census year. The coefficients on the industry dummy variables are what we use as the industry premia in constructing our $R$ measures.

The dependent variable in our analysis is the log change in industry-city-level employment rates. We construct the industry-level employment rate by summing the number of individuals working in that particular industry divided by the city working-age population. Using employment to population ratios means that we include individuals who are classified as being out of the labor force as being relevant for labor market tightness. This is consistent with previous work on matching functions (Blanchard and Diamond, 1989) and on local labor market conditions (Bartik, 2006). Nevertheless, we have assessed the sensitivity of our results to this assumption and found it to be robust to an alternative definition of employment rates that restricts the population to include only those individuals that report themselves as being in the labor force. For most of our estimates, we use decadal differences within industry-city cells for each pair of decades in our data (1980-1970, 1990-1980, 2000-1990) plus the 2007-2000 difference, pooling these together into one large dataset and including period specific industry dummies. In all the estimation results, we calculate standard errors allowing for clustering by city and year.\footnote{We cluster at the city-year level because this is the level of variation in our data. Clustering only by city has little effect on the estimates of standard errors that we report.}

\section{3 Results}

We begin the discussion of our results by presenting estimates of the first-stage, or reduced form, wage equation. These echo results presented in BGS where the focus is precisely on the estimation of the impact of industrial composition shifts on wages, though the specifications are not identical because our focus, here, is on the reduced form.\footnote{BGS focus on investigating and interpreting the impact of $\Delta R_{ct}$ on $\Delta \ln w_{ict}$. In BGS it is argued that the estimates imply that the impact of a change in industrial composition on the average wage in a city is approximately 3.5 times what is implied by a standard decomposition approach once spill-over effects are accounted for.}
The columns of Table 1 contain estimates for the first-stage wage equations. In Columns 1 and 2, we regress wage changes on $IV_{1ct}$ and $IV_{2ct}$, respectively. This and all subsequent specifications include a full set of year-by-industry dummies ($4 \times 144$), but we suppress the presentation of these coefficients for brevity. The key point from these columns is that both $IV_{1ct}$ and $IV_{2ct}$ are strong and highly significant determinants of $\Delta \ln w_{ict}$. Recall from our earlier discussion that $IV_{1ct}$ and $IV_{2ct}$ correspond to quite different parts of the variation in $\Delta R_{ct}$ but the theory implies that they should have the same effect on bargaining power and, hence, on wages. The estimated coefficients on the two variables are very similar, and we cannot reject the restriction that they are equal at any conventional significance level. We view this as a strong piece of supportive evidence for the model. In the last column of Table 1, we include both $IV_{1}$ and $IV_{2}$ to show that they are both individually helpful in predicting wages.

### 3.1 Estimates of the Job Creation Curve: Basic Results

In Table 2, we present estimates of our main equation of interest (14). As in Table 1, all the reported regressions include a full set of year-by-industry dummies. Column 1 reports OLS results. Both the coefficients on the wage and the city-level employment rate are positive and highly significant. This is the opposite of what our theory predicts for consistent estimates of the coefficients in (14). However, the employment rate and wage equations derived from the model imply that OLS estimation of this equation should not provide consistent estimates. Moreover, the fact that productivity shocks, $\epsilon_{ict}$, enter the wage and employment rate equation error terms suggests that the OLS regression coefficients are likely to be positive.

Columns 2-4 contain results from estimates of (14) using the $IV_{1}$ and $IV_{2}$ instruments discussed in section 1.4. As we saw in Table 1, the instruments perform well in the first-stage. F-statistics for wages are reported in the bottom rows of Table 2, supporting our claim that our instruments are good predictors of within-industry wage changes and we do not face weak instrument concerns.

The IV results indicate that labor costs are negatively associated with sector employment rates, as predicted by theory. The magnitude of the estimated coefficients on $\Delta \ln w_{ict}$ obtained from either $IV_{1}$ or $IV_{2}$ are nearly identical, and a standard over-id test fails to reject the null hypothesis of equality at any conventional significance level. As argued earlier, we view this result as being particularly important. From a theoretical point of view, bargaining implies that improvements in workers’ outside employment opportunities should have the same impact on wages regardless of whether the improvements arise from growth in a high paying industry in a locality (the variation emphasized in $IV_{1ct}$) or increases in industrial premia in existing industries (the variation emphasized in $IV_{2ct}$). Given this, we also expect labor demand responses estimated from either source of variation to be the same since employers are only concerned about the bargained wage. From an empirical point of view, this result provides an important test of our identifying assumptions.

---

27 The actual test statistic value is 0.17 with a p-value of 0.68.
Heuristically, since both instruments are valid under the same assumptions but rely on very different sources of variation, departures from these assumptions will be weighted differently by the two instruments, causing the estimates to diverge. The fact that we do not observe this provides a stringent test of the validity of our instrumental variables approach and is a strong piece of evidence in favor of the search and bargaining model.

The other key prediction from the model is that an increase in labor market tightness in a city (as represented by the city-level employment rate) should negatively affect within industry employment rates. Once we instrument, we do, in fact, find a strongly significant negative effect of $\Delta \ln \frac{E_{it}}{L_{it}}$ on $\Delta \ln \frac{C_{it}}{L_{it}}$. This is a striking result since one would normally expect a positive relationship between these variables. As we discussed earlier, it is difficult to reconcile this result with a standard neoclassical model but it is a clear prediction of a search and bargaining model.

We are now in a position to interpret the results. Consider a wage increase in a particular industry, holding overall employment rates constant. If the industry in question is not so large as to have a significant impact on overall employment rates, the estimates using IV1 and IV2 as instruments in Table 2 imply a labor demand elasticity at the industry level of about $-1$.

What about improvements of wages in a city more generally? Since all industries will adjust employment downward in response to a general wage increase, there will be feedback effects on overall employment rates. Allowing these equilibrium effects to play out implies a city-level labor demand elasticity of $\frac{E_{it}}{L_{it}}$ or of about $-0.30$ given our estimates. In other words, since $\varphi_3$ is predicted to be less than zero in a search and bargaining model, overall wage increases in a locality have a built in dampening effect on employment responses because they simultaneously increase the availability of workers. In our model, this leads to reduced search costs for firms (because vacancy contact rates are higher) or improved average entrepreneur quality. Thus, our estimates suggest that city-level job creation curves are relatively wage inelastic, with an increase in wages of 10% implying a reduction in the city-level employment rate of about 3%.

Recall that we can also obtain an estimate of the city-level demand elasticity through direct estimation of our city-level regression, (24). Estimates of (24) are presented in Table 3. This table has a similar format to those that proceed it, and also contains a full set of year dummies. IV estimates of the coefficient $\frac{E_{it}}{L_{it}}$ in columns (2)-(4) range from about $-0.27$ to $-0.31$. The estimates obtained using IV1 and IV2 are again nearly identical and a standard over-identification test again fails to reject the null hypothesis. Thus, in this specification, too, the results strongly support the search and bargaining model. Furthermore, the estimates of the city-level demand elasticities using the aggregated data are almost identical to what we just calculated using the estimated coefficients from specification (14). Since estimation of (14) and (24) use very different levels of variation (and since there is no mechanical reason the two specifications should provide the same results), we view the similarity of the estimates of the city-level elasticity obtained from each as a further piece of evidence supporting the search and bargaining model for understanding the wage-employment nexus.
4 Robustness and Specification Tests

In this section, we assess the sensitivity of our results to a variety of specification checks.

4.1 Exploring the Effects of Labor Force Size on Employment Determination

Table 4 contains results from our baseline specification (14) and our aggregated specification (24) where we include labor force growth as an additional control variable. Under the assumptions of the model (specifically, that the matching function exhibits constant returns to scale and that the number of entrepreneurs is proportional to the labor force), changes in the size of the labor force should have no impact on employment rates once we control for local demand conditions and labor costs. The estimated coefficient on labor force growth in these equations serves as a check on these assumptions. The first column shows OLS estimates, while in Columns 2-4 we instrument for changes in within-industry wage and city employment rates. In columns 1-4, we do not instrument the city’s labor force variable. Interestingly, when we instrument the wages and employment rate when including the labor force growth variable, the estimated coefficients on $\Delta \ln w_{ict}$ and $\Delta \ln \frac{E_{ct}}{L_{ct}}$ change very little from the results presented in Table 2. It should be kept in mind that since we are examining decadal differences, these results should be interpreted as the long-term consequences of increasing the size of a city’s labor force.

Since the growth in labor force is not likely to be exogenous, finding that it does not enter significantly in Columns 1-4 cannot be used to infer that it does not affect the employment rate, since its coefficient is likely biased. We attempt to address this possibility by constructing an instrument set for labor force growth that is based on long-term city climate variables. Since mobility is likely driven by local amenities, variation in local amenities would potentially provide a good set of instruments. However, most amenities (not related to employment and wages) are relatively constant over time, making them unhelpful as instruments in our difference specification. Nonetheless, measures of amenities can still be used as instruments in this case if the value of the amenity has changed over time. For example, if the value of living in a nice climate has increased over time then the level of the climate indicator variable can be used as an instrument variable for labor force growth.\footnote{This idea comes from Dahl (2002) who empirically tests a Roy (1951) model of self-selection of workers across states. He finds that while migration patterns of workers are partially motivated by comparative advantage, amenity differences across states also play a role in worker movements.} Building on this insight, we collected data from a number of sources to construct an instrument set consisting of average temperatures and precipitation for each city in our sample. Consistent with the idea that workers are increasingly drawn to cities by amenity factors, we find that indicators of mild climates are significant predictors of city labor force growth.\footnote{The validity of the climate instruments rests on the assumption that the relationship between city climate and city-industry job creation and cost advantages (the $\Omega$s and $\epsilon$s) is constant over time. In this case, the instruments should be correlated with these variables and not with the error term.}
The estimates in Column 5 of Table 4 show the results using all of the instruments including the climate variables. The first stage F-statistic on labor force growth, reported in the second last row of the table, is 24.0, indicating that we predict labor force growth quite well. The estimated coefficient (standard error) on the labor force growth variable is -0.12 (0.072), which is larger than the non-instrument results but still not statistically significant. The estimated coefficients on $\Delta \ln w_{ict}$ and $\Delta \ln \frac{E_{ict}}{l_{ict}}$, are slightly lower, but still imply a city labor demand elasticity of $\frac{-0.27}{1+0.28} = -0.34$, which is in line with our previous estimates.

In Column 6, we report results from the city-level specification (24) with labor force growth included and using the climate instruments. This result supports the idea that a job creation curve – which represents a trade-off between wages and employment rates – is likely a better specification for examining the wages effect on employment than a more traditional labor demand specification where the dependent variable would be the level of employment.

### 4.2 Exploring Worker Heterogeneity

The model we developed in section 1 conceptually applies to workers of a single skill group. In section 1.6 we discussed how we address worker heterogeneity while at the same time focusing on the workforce as a whole. In this section, we assess this approach in two ways. First, we evaluate the sensitivity of our results to including variables designed to capture changes in the skill distribution of a city’s labor force. As discussed earlier, in a version of the model with perfectly substitutable bundles of efficiency units of work, the skill distribution of the labor force can affect job creation. We argued that we expect this effect to be second order in size but we wish to assess that expectation. Second, in keeping with the conceptual idea that the model may apply best to workers of a single type, we estimate our basic specification separately for workers with high school education or less and those with some post secondary or more.

Table 5 presents results obtained by adding additional regressors to capture changes in the skill distribution of a city’s workforce. The first variable we construct is the average efficiency units per person in a city. We essentially calculate efficiency units for a person type defined by experience, education, gender and immigrant status as the average real wage over our entire period for people of that type, and then assign efficiency units to each person in a city based on their type.\(^{30}\) Increases in this variable indicate that the workers in a city have become, on average, more productive and is designed to capture the effect that a firm opening a new vacancy has a higher probability of meeting a higher quality worker. We also construct an instrument designed to capture plausibly exogenous movements in this variable. To do this, we draw on literature that uses “enclaves” to predict immigration flows. In particular, we exploit the fact that immigrants from different sending countries have, on aver-

---

\(^{30}\) For additional details on how we calculate efficiency units, see Appendix B.
age, different educational attainment as well as other observable characteristics that influence a worker’s efficiency weight. We construct this instrument as follows: we assume immigrants from sending country $h$ entering the country over a particular decade, denoted by $M_{ht}$, choose cities based to some extent on where previous waves of immigrants from the same sending country had settled. Denote the fraction of immigrants from sending country $h$ living in city $c$ at time $t$, as $\lambda_{hct}$. The predicted number of immigrants that will move to city $c$ in year $t$, $\hat{M}_{ct}$, can be written as:

$$\hat{M}_{ct} = \sum_h \lambda_{hct-1} \cdot M_{ht}.$$ 

Similarly, we can construct the predicted number of workers in efficiency units that move to city $c$ in year $t$ as $\hat{M}_{EU}^{ct} = \sum_h \lambda_{hct-1} \cdot M_{ht} \cdot \omega_{ht-1}$, where $\omega_{ht-1}$ is the efficiency weight per worker from sending country $h$ in the base year. To predict changes in the average efficiency units per worker, assuming no other changes in population, we construct the following instrument:

$$IV_{EU}^{ct} = \left( \frac{\hat{M}_{EU}^{ct} - EU_{ct-1}}{\hat{M}_{ct}} \right) \cdot \frac{\hat{M}_{ct}}{\hat{M}_{ct} + L_{ct-1}}, \quad (25)$$

where $\frac{\hat{M}_{EU}^{ct}}{\hat{M}_{ct}}$ is the predicted average efficiency units per worker arriving in city $c$ in year $t$ and $EU_{ct-1}$ is the actual average efficiency units in city $c$ in year $t - 1$.31

The results that include changes in efficiency units per worker as an additional control are presented in Columns 1-4 of Table 5. In the first column, where all variables are treated as if exogenous, the change in efficiency units per worker does not enter significantly. IV results are given in Columns 2-4, where we include $IV_{EU}^{ct}$ in the instrument set. In line with previous literature, the immigration enclave instrument predicts changes in a city’s skill composition quite well.32 Nevertheless, in no specification is the skill variable significant, and, more importantly, it alters the magnitude of the estimated demand elasticities very little. To further probe sensitivity of our results to changes in city skill distribution, Columns 5-8 add alternative measures of a city’s skill. In Columns 5 and 6, we include the change in the fraction of college graduates as an additional control. When treated exogenously, as in Column 5, it enters significantly but does not change the main conclusions regarding demand elasticities. In Column 6, we instrument the change in the proportion of college graduates with an enclave instrument similar to (25).33 This results in imprecise estimates that are not significantly different from zero despite a strong first-stage. In the remaining Columns, 7 and 8, we include the change in the proportion of workers with education greater than high school. Again, inclusion of this variable does not alter the main conclusions of the paper. We conclude that changes in a city’s skill distribution have, at best, only a second order effect on job creation and do not appreciably affect the estimated magnitude of our key parameters.

31The formulation of this instrument is similar to Doms and Lewis (2006), and in the same spirit as Card and DiNardo (2000) and Card (2001, 2009), among others.

32The first-stage $t$-ratio on $IV_{EU}^{ct}$ in the change in efficiency units per worker equation is over 8.0 in all specifications.

33In this case, the instrument is constructed in exactly the same way as Doms and Lewis (2006).
In Table 6 we estimate our basic specification separately by education group. The education groups we consider are those with high school education or less and those with some post secondary or more.\textsuperscript{34} When we perform this exercise, we are assuming that there are two completely segregated markets defined by education.\textsuperscript{35} The dependent variable in Table 6 is the change in log city-industry employment rates for a particular education group. Similarly, wages and their instruments are constructed separately by education group.\textsuperscript{36} However, we maintain the use of aggregate, city-wide employment rates (over all education groups) to capture the effects of limited entrepreneurial talent (which should operate at the city level) and vacancy contact rates.\textsuperscript{37} Columns (1)-(4) pertain to the low-education group and columns (5)-(8) to the high-education group. The results for the low education group are very similar to those for the full sample. The results for the (smaller) post-secondary group are more erratic but tend to imply a similar sized wage elasticity.

4.3 Further Model Implications

To this point we have focused on how changes in wages, driven by changes in the bargaining power of workers, affect the employment rate in a city. The main mechanism by which a change in wages affects employment in our model is through inciting individuals to become entrepreneurs and create jobs. When wages are high, the profit to creating jobs is low and fewer individuals should choose to become entrepreneurs. In such a case, we should observe a low ratio of entrepreneurs-to-workers as only very efficient individuals should become entrepreneurs. In this section we want to explore whether observable entrepreneurial activity is consistent with this mechanism. In particular we will examine how changes in wages induces changes in the ratio of entrepreneurs to employees. Our measure for entrepreneurs will be the number of self-employed individuals in an industry-city cell. While self-employment is not a perfect measure of entrepreneurship, it is the most commonly used measure in the literature and we follow this tradition here. We exclude professionals from our measure of self-employed as these are represent mainly by physicians and lawyers who do not likely reflect the mechanism emphasized in the model. Including the professionals does not affect the main result we describe below.

Recall from section 1.2 that the number of entrepreneurs in industry \( i \) in city \( c \) –
To get an expression for the ratio of entrepreneurs-to-employees, which we will refer to as entrepreneurial intensity, we divide equation (26) by $E_{ct}$. The log-linear approximation for $S_{ict}/E_{ct}$ can then be expressed as

$$\Delta \frac{S_{ict}}{E_{ct}} = \rho_{it} + \rho_2 \Delta V_{ict} + \rho_3 \Delta \ln \frac{E_{ct}}{E_{ct}} + \Delta \Omega_{ict},$$  

where $\rho_2 > 0$ and $\rho_3 < 0$. We can now use equation (12) to get the following expression:

$$\Delta \frac{S_{ict}}{E_{ct}} = (\rho_{it} + \rho_2 \tilde{\alpha}_{it}) + (\rho_2 \alpha_2) \Delta \ln w_{ict} + (\rho_3 + \rho_2 \alpha_3) \Delta \ln \frac{E_{ct}}{E_{ct}} + \rho_2 \alpha_4 \Delta \epsilon_{ict} + \Delta \Omega_{ict}$$

(28)

where $(\rho_2 \alpha_2)$ and $(\rho_3 + \rho_2 \alpha_3)$ are predicted to be negative. This equation will not be estimated consistently by OLS, as the regressors are correlated with the error term. In particular, we would expect productivity changes in the error term to be positively correlated with wage changes. As the error term in (28) is of the same structure as in (12), the set of instruments we used to estimate the job creation equation ($IV_1$, $IV_2$ and $IV_3$) will provide consistent estimates of (28) under the same identifying assumptions used earlier.

Table 7 presents estimates of Equation (28). Column 1 contains estimates of the relationship obtained by OLS. The OLS estimated effect of wages on entrepreneurial intensity is close to zero, but as noted above, we expect this estimate to be biased. In Column 2 we use $IV_1$ and $IV_3$ to instrument the two regressors. In Columns 3 we use $IV_2$ and $IV_3$ and in Column 4 we $IV_1$, $IV_2$ and $IV_3$. Importantly, using any of these combinations of instruments, the estimated effect of wages on entrepreneurial intensity is significantly negative. Moreover, the coefficient is very stable across the three columns, with the over-id test reported in Column 4 showing that the over-identifying restriction is easily accepted by the data. As in our estimates of the job creation curve, we view the over-id test as a test of the validity of the model including our assumptions for the driving forces. We view it as quite telling that we find evidence in favor of the model even when we switch to a very different dependent variable. While the effect of wages on self-employment is quite precisely estimated, the estimated effect of market tightness is imprecisely estimated. The observed negative effect of wages on entrepreneurial activity provides some direct evidence in support of the idea whereby higher wages reduce employment by reducing the incentive for individuals to become entrepreneurs and create jobs.

One of the key assumptions underlying our analysis is that entrepreneurs are proportional to the population, and that increasing the population in a city tends simply to lead to a replication of the employment structure in the city. This assumption was important for the results that employment determination should be stated in terms of employment rates instead of employment levels. This assumption also implies that entrepreneurial intensity should be unaffected by an exogenous increase
in the population. In Columns 5 and 6 of Table 7 we explore this implication by adding labor force growth as an additional regressor to equation (28). In these three columns we instrument the wage and the employment rate using $IV_1$, $IV_2$ and $IV_3$ as instruments. In Column 5 we do not instrument the labour force growth rate. In Column 6 we instrument labour force growth using the climate variables presented earlier as instruments. In both of the specifications, the effect of population growth is very small and not statistically significant at conventional levels. This supports the idea that entrepreneurs may be a scarce factor of production but that their supply appears to increase in proportion close to that of the population.

The combination of the result that entrepreneurs are proportional to the population and the result that population size does not help determine employment rates have important implications for addressing the puzzle set out at the beginning of the paper: that is, why estimates using changes in policy parameters tend to imply inelastic labor demand curves while estimates based on migration shocks tend to imply very elastic curves. The policy shocks correspond to changes in labor costs and so, would be expected to trace out the slope of the job creation curve. In this sense, the fact that we obtain similar estimates from very different variation is encouraging. On the other hand, with a constant returns to scale matching function and entrepreneurs proportional to the population, an increase in the size of the population will not affect the equilibrium in employment rate - wage space since under these assumptions what matters is the tightness of the labor market not its size. Thus, when an immigration shock hits a local market we should see employment rise enough to restore the employment rate to its equilibrium level and the wage rate remain unchanged (after a period of adjustment). Plotted in employment level - wage space, the resulting relationship would be very flat and might be interpreted as revealing a very elastic labor demand curve. In the search and bargaining context, instead, this is simply a by-product of the main adjustments witnessed in employment rate – wage space. While much attention has been paid to Card's result that the Mariel boat-lift did not alter wages in the Miami labor market, less has been made of his findings that the employment rate also returned to its previous level within a few years. We view this combination as fitting well with what we find.

5 Conclusion

In this paper, we extend and estimate an empirically tractable version of a search and bargaining model. Our goal is to highlight the implications of such a model for labor demand and to provide estimates of the responsiveness of employment outcomes to changes in average wages. In a search and bargaining model, labor demand is determined by points along the job creation curve, which is implicitly defined by a zero marginal profit condition for the creation of a vacancy. According to this condition, when wages rise the tightness of the labor market must fall in order to maintain the value of creating jobs. Therefore, the job creation curve defines a relationship between wages and employment rates rather than employment levels, as in more standard set-ups. We argue that this seemingly small difference has substantial im-
lications. Chief among these is that shifts in labor supply and labor costs can produce very different labor market outcomes; that is, supply and wage shocks do not imply movements along the same demand curve in a search and bargaining model. This insight has the potential to explain some of the differences in labor demand elasticities that are presented in the literature.

In order to empirically evaluate the relevance of the search and bargaining framework, we extend an otherwise standard Pissarides (2000) model in several directions. First, our model includes multiple local labor markets linked through trade and labor mobility. There is substantial variation in employment levels and rates across cities, allowing for the identification of city-level job creation curves. Second, we extend the model to include multiple sectors, which is crucial for our identification strategy. Using insights developed in Beaudry, Green, and Sand (2009), we use predicted industrial composition shifts to identify movements in average city wages induced by shifts in the outside options of workers. In a search and bargaining model, improvements in the outside employment opportunities of workers increases the bargained wage across all sectors within a locality. Finally, we follow Fonseca, Lopez-Garcia, and Pissarides (2001) in extending the standard model to include heterogeneous talent across the population in terms of abilities to create jobs in different industries. With this extension, the job creation curve may be less than perfectly elastic because of both search costs and the limited availability of job creators.

A key feature of this model is that it implies tight testable implications, as well as an over-identifying restriction. We use U.S. Census data from 1970-2007 to investigate whether city-level labor market outcomes conform to these restrictions. Working mainly at the industry-city level, our approach relies on comparing industry level changes in employment rates between cities with different changes in within-industry wages. We look at effects over periods of 10 years and, therefore, our estimates should be interpreted as representing long-run labor market outcomes. Importantly, we find that the model’s main over-identifying restriction is easily passed in the data. While this observation does not necessarily prove that the theory is correct, we nevertheless believe that it provides compelling evidence in favor of the model. Based on this, we view estimates derived from this model as a reliable basis for assessing the impact of wage changes on employment outcomes.

The model implies two types of labor demand elasticities. The first corresponds to the effect of an increase in the cost of labor on a particular sector’s employment rate while holding the overall tightness of the labor market in the city constant. Our estimate of this partial equilibrium elasticity is close to $-1$. We also examine how the local labor market as a whole reacts to a general increase in wages, allowing for interaction across sectors through the availability of workers and job creators. For this aggregate elasticity we obtain an estimate of approximately $-0.3$. We view the aggregate elasticity as the relevant concept for most policy discussions and see our estimate as indicating a reasonable but relatively inelastic relationship. For example, our estimates indicate that to obtain an increase in the employment rate of 1%, it is necessary to cut wage cost by 3%. Our model suggests that the somewhat low elasticity partly reflects a weak propensity for individuals to become more entrepreneurial and create more jobs as labor costs are reduced. This could arise either
because the supply of new entrepreneurs is quite inelastic or because the creation of more jobs by existing entrepreneurs is limited by span of control problems. We hope to explore such mechanisms in more depth in future research.

Finally, the model provides a simple way to reconcile different estimates of the elasticity of labor demand obtained from policy shifts, such as minimum wage or payroll tax changes, versus those obtained from examining the response of wages to supply shifts. In a neo-classical framework both these approaches should identify the slope of the labour demand curve. However, the empirical literature generally comes to very different conclusion depending on which variation is used; with studies based on labour supply shifts suggesting an almost infinite elasticity of labour demand while those based on policy shifts suggest a much smaller elasticity. Within a search and bargaining model, these two sources of variation have quite different implications. On the one hand, a payroll tax should contribute to an increase in labor costs and, thus, can be used to identify the slope of the job creation curve. In this sense, it is encouraging that our estimated elasticity of the job creation curve broadly fits with the studies examining the effects of such policy interventions. On the other hand, an increase in the size of the labor force in the search and bargaining model does not trace out the equivalent of the labor demand curve. Instead, an increase in labor force size (perhaps due to immigration) should not change the equilibrium employment rate or wage, but should simply lead to an increase in the level of employment and an increase in the number of job creators. This is precisely the pattern we find when looking at cross-city outcomes.

All models include an unrestricted set of year × industry dummies.
A Consistency

We are interested in the conditions under which our instruments can provide consistent estimates. Apart from the instruments being correlated with $\Delta R_{ic}$ and $\Delta w_{ic}$, the condition we require for a given instrument, $Z_c$, is

$$\lim_{C,l \to \infty} \frac{1}{I} C \sum_i \sum_c Z_c \Delta \zeta_{ic} = 0. \quad (A-1)$$

We will handle the limiting arguments sequentially, allowing $C \to \infty$ first.\(^{38}\) Recall that $IV_1$ is given by:

$$Z_c = \sum_j \eta_{jc} (g^*_j - 1)(w_j - w_1), \quad (A-2)$$

where $g^*_j = \frac{1+g_j}{\sum_k \eta_{kc} (1+g_k)}$ and $g_j$ is the growth rate in employment in industry $j$ at the national level. Given this, (A-1) becomes:

$$\lim_{C \to \infty} \frac{1}{I} C \sum_j (w_j - w_1) \sum_c \eta_{jc} (g^*_j - 1) \sum_i \Delta \zeta_{ic}. \quad (A-3)$$

We can derive an equation for shares as:

$$\eta_{ic} = \frac{\hat{\Omega}_{ic} \cdot F(V_{ic}^v)}{\sum_i \Omega_{ic} \cdot F(V_{ic}^v)} \quad (A-4)$$

Taking linear approximation, again, around the point where $\Omega_{ic} = \epsilon_{ic} = 0$ yields the following expression:\(^{39}\)

$$\eta_{ic} \approx \frac{1}{I} + \pi_1 \left( \epsilon_{ic} - \frac{1}{I} \sum_i \epsilon_{ic} \right) + \pi_2 \left( \Omega_{ic} - \frac{1}{I} \sum_i \Omega_{ic} \right) \quad (A-5)$$

The $\pi$s are positive coefficients obtained from linear approximation. We can decompose the $\epsilon$s and $\Omega$s into absolute and comparative advantages, $\epsilon_{ic} = \hat{\epsilon}_c + v_{ic}^\epsilon$ and $\Omega_{ic} = \hat{\Omega}_c + v_{ic}^\Omega$, which gives:

$$\eta_{ic} = \frac{1}{I} + \pi_1 \cdot v_{ic}^\epsilon + \pi_2 \cdot v_{ic}^\Omega \quad (A-6)$$

Similarly, substituting $\epsilon_{ic} = \hat{\epsilon}_c + v_{ic}^\epsilon$ and $\Omega_{ic} = \hat{\Omega}_c + v_{ic}^\Omega$ into the last term of (A-3), gives:

$$\sum_i \Delta \zeta_{ic} = \lambda_1 \cdot I \cdot \Delta \hat{\epsilon}_c + \lambda_2 \cdot I \cdot \Delta \hat{\Omega}_c, \quad (A-7)$$

which depends only on the increments of the absolute advantage components. From equation (A-6), the city-industry shares depend only on the relative advantage components. Thus, (A-3) equals zero provided that $E(\Delta \hat{\epsilon}_c) = E(\Delta \hat{\Omega}_c) = 0$, and that $\Delta \hat{\epsilon}_c$ and $\Delta \hat{\Omega}_c$ are independent of past values of the relative advantage components, $v_{ic}^\epsilon$ and $v_{ic}^\Omega$. In other words, general improvements in a city must be unrelated to past industry relative advantages.

\(^{38}\)Throughout this appendix we omit the $t$ subscript for simplicity.

\(^{39}\)Recall that if $\Omega_{ic} = \epsilon_{ic} = 0$ then the industry shares are equal across cities. We further assume, for simplicity, that the shares are equal to $\frac{1}{I}$. 

39
Similarly, the relevant condition when using $IV_2$ is given by

$$
\lim_{C \to \infty} \frac{1}{C} \sum_j \Delta(w_j - w_1) \sum_c \eta_{jc} \sum_i \Delta \xi_{ic},
$$

(A-8)

and the same conditions ($\Delta \xi_c$ to be independent of past values of $\nu_{ic}^\xi$ and of $\nu_{ic}^{\Omega}$) ensure that this condition equals zero.

An important implication follows from this discussion. If the key identifying assumption underlying the $IV$s does not hold (i.e., changes in absolute advantage are not independent of past comparative advantages) then the two $IV$s will place different weight on the problematic correlation (between $\Delta \xi_c$ and $\nu_{ic}^\xi$). In particular, $IV_1$ use the weights $\nu_{it-1}$, while $IV_2$ uses the weights $\Delta \nu_{it}$) and, therefore, estimates based on $IV_1$ and $IV_2$ should diverge.
B Data (Not For Publication Appendix)

The Census data was obtained with extractions done using the IPUMS system (see Ruggles, Sobek, Alexander, Fitch, Goeken, Hall, King, and Ronnander (2004)). The files were the 1980 5% State (A Sample), 1990 State, 2000 5% Census PUMS, and the 2007 American Community Survey. For 1970, Forms 1 and 2 were used for the Metro sample. The initial extraction includes all individuals aged 20 - 65 not living in group quarters. All calculations are made using the sample weights provided. For the 1970 data, we adjust the weights for the fact that we combine two samples. We focus on the log of weekly wages, calculated by dividing wage and salary income by annual weeks worked. We impute incomes for top coded values by multiplying the top code value in each year by 1.5. Since top codes vary by State in 1990 and 2000, we impose common top-code values of 140,000 in 1990 and 175,000 in 2000.

A consistent measure of education is not available for these Census years. We use indicators based on the IPUMS recoded variable EDUCREC that computes comparable categories from the 1980 Census data on years of school completed and later Census years that report categorical schooling only. To calculate potential experience (age minus years of education minus six), we assign group mean years of education from Table 5 in Park (1994) to the categorical education values reported in the 1990 and 2000 Censuses.

Census definitions of metropolitan areas are not comparable over time since, in general, the geographic areas covered by them increase over time and their definitions are updated to reflect this expansion. The definition of cities we use attempts to maximize geographic comparability over time and roughly correspond to 1990 definitions of MSAs provided by the U.S. Office of Management and Budget. To create geographically consistent MSAs, we follow a procedure based largely on Deaton and Lubotsky (2001) which uses the geographical equivalency files for each year to assign individuals to MSAs or PMSAs based on FIPs state and PUMA codes (in the case of 1990 and 2000) and county group codes (for 1970 and 1980). Each MSA label we use is essentially defined by the PUMAs it spans in 1990. Once we have this information, the equivalency files dictate what counties to include in each city for the other years. Since the 1970 county group definitions are much coarser than those in later years, the number of consistent cities we can create is dictated by the 1970 data. This process results in our having 152 MSAs that are consistent across all our sample years. Code for this exercise was generously provided by Ethan G. Lewis. Our definitions differ slightly from those in Deaton and Lubotsky (2001) in order to improve the 1970-1980-1990-2000 match.

We use an industry coding that is consistent across Censuses and is based on the IPUMS recoded variable IND1950, which recodes census industry codes to the 1950 definitions. This generates 144 consistent industries. We have also replicated our results using data only for the period 1980 to 2000, where we can use 1980 industry definitions to generate a larger number of consistent industry categories.

---

42 The program used to convert 1990 codes to 1980 comparable codes is available at
also able to define more (231) consistent cities for that period.

We create a variable to proxy for the cost of housing in a city by using a measure of the rental rate of a two or three bedroom apartment in that city. To construct this variable, we use the Census variable for ‘contract rent’ and restrict it to the reported rent for two or three bedroom apartments in each of our MSAs. This is a similar procedure to that used recently by Moretti (2010). See that paper for a discussion on the appropriateness of this measure for local housing costs.

We construct efficiency units in the same manner as Katz and Murphy (1992). We begin by dividing the data, in each year, into demographic cells defined by potential experience (5 categories), education (4 categories), gender, race and immigrant status. We then calculate the average weekly wage and share of employment for each cell by year. We create a set of fixed-weights by averaging the employment shares for each demographic group across years, and construct an index of wages by year by taking the fixed-weighted average of wages in each year. We then divide cell-by-year wages by this index, and average across years for each demographic cell to obtain our measure of efficiency weights. When calculating efficiency units of workers, we use the efficiency weight multiplied by the sampling weight for each worker.

\section*{B.1 Enclave Instrument (Not for Publication Appendix)}

The construction of the enclave instrument is similar to that of Doms and Lewis (2006) and uses their origin country groupings. The country of origin groups are (1) Mexico, (2) Central America, (3) South America, (4) Central Europe and Russia, (4) Caribbean, (5) China, (6) South East Asia, (7) India, (8) Canada, U.K., and Australia, (10) Africa, (11) Korea and Japan, (12) Pacific Islands, (13) Israel and NW Europe, (14) Middle East, (15) Central Asia, (16) Cuba, and (17) Souther Europe and can be identified from the IPUMS variable bpl "Birthplace [general version]".

To identify the inflows of immigrants, we use the IPUMS variable yrimmig "Year of immigration".

\section*{B.2 Climate Instrument}

The city level climate variables were extracted from "Sperling's Best Places to Live" (http://www.bestplaces.net/docs/DataSource.aspx). Their data is compiled from the National Oceanic and Atmospheric Administration. The variables we use in this paper are the average daily high temperatures for July and January in degrees Fahrenheit. Alternative variables available from the same source are annual rainfall in inches and a comfort index. The comfort index is a variable created by "Sperling's Best Places to Live" that uses afternoon temperature in the summer and local humidity to create an index in which higher values reflect greater "comfort". We have http://www.trinity.edu/bhirsch/unionstats . That site is maintained by Barry Hirsch, Trinity University and David Macpherson, Florida State University. Code to convert 2000 industry codes into 1990 codes was provided by Chris Wheeler and can be found at http://research.stlouisfed.org/publications/review/past/2006. See also a complete table of 2000-1990 industry crosswalks at http://www.census.gov/hhes/www/ioindex/indcswk2k.pdf
also compiled climate data from an alternative source to use as a robustness check. These data come from "CityRating.com’s" historical weather data, and include variables on average annual temperature, number of extreme temperature days per year, humidity, and annual precipitation. Data from this source could only be collected for 106 cities, and, therefore, not included in this analysis.

C Worker Heterogeneity

Consider a simple search and bargaining model in which there are two types of workers: high- and low-skill. Let $\theta$ denote the fraction of high-skill workers and $\eta_H > 1$ and $\eta_L = 1$ denote productivity of high {H} versus low {L} skill workers.

The Bellman equations for firms can be written as:

$$\rho V^v = -r + \phi \cdot \left( \theta \cdot V^f_H + (1 - \theta) \cdot V^f_L - V^v \right)$$  \hspace{1cm} (C-9)

$$\rho V^f_i = \eta_i \cdot p - w_i + \delta \cdot (V^v - V^f_i)$$ \hspace{1cm} (C-10)

where $p$ is the price of the output, and $w_i$ is the wage paid for $i \in \{H, L\}$.

Combining (C-9) and (C-10), gives the value of a vacancy:

$$\rho V^v = \frac{-(\rho + \delta) \cdot r + \phi \cdot (\theta \cdot (\eta_H \cdot p - w_H) + (1 - \theta) \cdot (p - w_L))}{\rho + \delta + \phi}.$$ \hspace{1cm} (C-11)

Workers of each skill type of the following Bellman equations:

$$\rho U^u_i = b + \psi \cdot (U^e_i - U^u_i)$$ \hspace{1cm} (C-12)

$$\rho U^e_i = w_i + \delta \cdot (U^u_i - U^e_i)$$ \hspace{1cm} (C-13)

for type $i \in \{\text{High, Low}\}$. Wages are set according to the rule $(1 - \beta)(U^e_i - U^u_i) = \beta(V^f_i - V^v)$. This gives

$$w_i = (1 - \beta) \cdot \rho U^u_i + \beta \cdot (\eta_i p - \rho V^v).$$ \hspace{1cm} (C-14)

The Bellman equations for workers gives $\rho U^u_i$ as

$$\rho U^u_i = \frac{b \cdot (\rho + \delta) + \psi \cdot w_i}{\rho + \delta + \psi}.$$ \hspace{1cm} (C-15)

Hence, wages can be written as:

$$w_i = \beta \Psi (\eta_i \cdot p - \rho V^v) + \frac{(1 - \beta) \cdot \Psi \cdot b (\rho + \delta)}{\rho + \delta + \beta \Psi}.$$ \hspace{1cm} (C-16)

for each type where $\Psi = \frac{\rho + \delta + \psi}{\rho + \delta + \beta \Psi}$. Then the wage differential between high- and low-skill workers is:

$$w_H - w_L = \beta \Psi p \cdot (\eta_H - 1) > 0.$$ \hspace{1cm} (C-17)

\textsuperscript{43}Here, we assume that firms meeting either high- or low-skill workers will form matches. This can be seen as a restriction that $\eta_H$ cannot be too large.
We can also calculate the difference in the flow profits for a firm meeting a high-versus low-skill worker:

\[(\eta_H \cdot p - w_H) - (p - w_L) = p \cdot (\eta_H - 1) \cdot (1 - \beta \Psi) > 0 \quad (C-18)\]

Notice that we can write the high-skill wage in terms of the low-skill wage, which rationalizes the use of regression adjusted wages. Also, we can rearrange the job creation equation so that it depends on low-skill wage, plus \( \theta \) times the difference in flow of profits. This reduces the value of a vacancy to a function of three variables \( \rho V = G(\theta, \frac{E}{L}, w_L; \beta, \eta_i, \rho, \delta) \) where \( \phi = \phi(\frac{E}{L}) \) and \( \psi = \psi(\frac{E}{L}) \) are a function of the employment rate.

Setting \( r = 0 \), we can write

\[\rho V = \frac{\phi}{\rho + \delta + \phi} \cdot (\theta \cdot p \cdot (\eta_H - 1) \cdot (1 - \beta \Psi) + p - w_L). \quad (C-19)\]

The term interacting with the skill variable, \( \theta \), in equation (C-19) will be proportional to \((1 - \beta \Psi)\), which is equal to:

\[1 - \beta \Psi = \frac{(1 - \beta)(\rho + \delta)}{\rho + \delta + \beta \psi}. \quad (C-20)\]

If \( \rho + \delta \) is small relative to \( \psi \) (Blanchard, 1998), this term will also be small. Hence, we assume these skill effects only secondary and we can focus on \( \rho V = \hat{G}(\frac{E}{L}, w_L; \beta, \eta_i, \rho, \delta) \). This justifies using efficiency wages while not making any adjustments for \( \frac{E}{L} \) in the baseline empirical work. We assess the sensitivity of this assumption in a robustness section by including measures of city skill, skill breakdowns, and efficiency units. None of our results seem to be sensitive to any of these alternative specifications.

## D Worker Mobility (Not for Publication Appendix)

The purpose of this section is to extend our search and bargaining model to include worker mobility and to demonstrate that this extension does not change the main implications of our model. We consider two extensions of the model. In the first case, suppose unemployed workers have the option of occasionally switching cities. When this situation arises, with probability \( \mu_1 \), workers choose to move to the city that maximizes their expected utility, \( \max_c U^u_c \). To incorporate this extension, we can write workers’ unemployment Bellman equation as:

\[\rho U^u_c = b + \tau_c + (1 - \mu_1)\psi_c \cdot \left( \sum_j \eta_{jc}U^e_{jc} - U^u_c \right) + \mu_1 \cdot (\max_c U^\beta_c - U^u_c), \quad (D-21)\]

where we have assumed that \( \mu = 0 \) to simplify exposition.\(^{44}\) The outside options of workers are now changed and wage negotiation will take this into account. Importantly, the form of this change does not alter any of our results because \( \max_c U^u_c \) does not depend on workers’ initial location and, therefore, is captured in our empirical specifications by year-by-industry dummy variables. It should be noted that

\(^{44}\)This is without loss and has the implication that unemployed flows depend only on city rather than industry-city.
in this case, however, the parameters we estimate will have a slightly different interpretation because they will depend on \( \mu_1 \) (the ease of switching cities). Moreover, since in equilibrium workers will equalize expected utility across locations the term \( \max_c U^u_c - U^u_c \) in equation D-21 will equal zero. Therefore, the equilibrium equations derived in the model section of this paper are not affected by this extension of worker mobility.

In the second extension, we include housing prices and local amenities, as in Roback (1982). We continue to allow workers to search across cities and choose the city that maximizes expected utility, as above. When doing so, workers take into account local housing costs and amenities. To incorporate this extension, assume that workers care about wages, the price of housing in a city, \( p_{hc} \), and about a local amenity, \( \Psi_c \). In this case, a worker’s (indirect) flow utility when employed in industry \( i \) in city \( c \) could be expressed as, \( w_{ic} - \vartheta p_{hc} + \Psi_c \). Accordingly, his or her flow utility when unemployed will be given by \( b + \tau_c - \vartheta p_{hc} + \Psi_c \). The first thing to notice about this extension is that housing prices do not directly impact wage negotiation because housing costs are incurred in both the employed and unemployed state. In order for expected utilities to equalize across cities, housing prices must adjust. To capture this, we summarize the functioning of the housing market by assuming that housing prices can be expressed as a positive function of the population of a city and of amenities, given by:

\[
p_{hc} = d_0 + d_1 \cdot L_{ct} + d_2 \cdot \Psi_c.
\]

It is straightforward to derive an expression for housing prices, \( p_{hc} \), that depends on local expected wages (and hence, on \( R_{ct} \)), amenities, and employment rates or labor market tightness. Housing prices will adjust such that a city with a favorable composition of jobs (due to the \( \Omega_s \)s and \( \epsilon_s \)s) and higher amenities have benefits that are captured by local landowners. Wage differences across cities will not be equalized because in-migration will drive up local housing costs causing the movement of workers between cities to stop before nominal wage equalization occurs. We conclude this section by noting that the forces emphasized in our model have testable implications for labor mobility and housing prices, but do not alter the main conclusions of our baseline model.

### E Selection Correction (Not for Publication Appendix)

The approach we use to address the issue of selection on unobservables of workers across cities follows Dahl (2002). Dahl argues that, under a sufficiency assumption, the selection-related error mean term in the wage equation for individual \( i \) can be expressed as a flexible function of the probability that a person born in \( i \)’s state of birth actually chooses to live in city \( c \) in each Census year.\(^{45}\) Dahl’s approach is a

\(^{45}\)This sufficiency assumption essentially says that knowing the probability of an individual’s observed or “first-best” choice is all that is relevant for determining the selection effect, and that the probabilities
two-step procedure that first requires estimates of the probability that \( i \) made the observed choice and then adds functions of these estimates into the wage equation to proxy for the error mean term. Dahl also presents a flexible method of estimating the migration probabilities that groups individuals based on observable characteristics and uses mean migration flows as the probability estimates. We closely follow Dahl’s procedure aside from several small changes to account for the fact that we use cities rather than states and to account for the location of foreign born workers.

Dahl’s approach first groups observations based on whether they are "stayers" or "movers". Dahl defines stayers as individuals that reside in their state of birth in the Census year. Since we use cities instead of states, we define stayers as those individuals that reside in a city that is at least partially located in individual’s state of birth in a given Census year. Movers are defined as individuals that reside in a city that is not located in that individual’s state of birth in a given Census year. We also retain foreign born workers, whereas Dahl drops them. For these workers, we essentially treat them as "movers" and use their country of origin as their "state of birth".\(^{46}\) Within the groups defined as stayers, movers, and immigrants, we additionally divide observations based on gender, education (4 groups), age (5 groups), black, and hispanic indicators. Movers are further divided by state of birth. For stayers, we further divide the cells based on family characteristics.\(^{47}\) Immigrants are further divided into cells based on country of origin as described above.

As in Dahl (2002), we estimate the relevant migration probabilities using the proportion of people within cells, defined above, who made the same move or stayed in their birth state. For each group, we calculate the probability that an individual made the observed choice and for movers, we follow Dahl in also calculating the retention probability (i.e. the probability that individual \( i \) was born in a given state, and remained in a city situated at least partly in that state in general). For movers, the estimated probabilities that individuals are observed in city \( c \) in year \( t \) differ based on individuals' state of birth (and other observable characteristics). Thus, identification of the error mean term comes from the assumption that the state of birth does not affect the determination of individual wages, apart from through the selection term. For stayers, identification comes from differences in the probability of remaining in a city in ones birth state for individuals with different family circumstances. For immigrants, we assign the probability that an individual was observed in city \( c \) in a given Census year using the probabilities from immigrants with the same observable characteristics in the preceding Census year.\(^{48}\) This follows the type of ethnic enclave assumption used in several recent papers on immigration, essentially using variation based on the observation that immigrants from a particular region tend to migrate to cities where there are already communities of people with their background.

\(^{46}\)We use the same country of origin groups as for the enclave instrument.

\(^{47}\)Specifically, we use single, married without children, and married with at least one child under the age of 5.

\(^{48}\)For cities in the 1980 Census not observed in the 1970 Census, we use the 1980 probabilities.
Having estimated the observed choice or "first-best" choice of stayers, movers, and immigrants and the retention probability for movers, we can then proceed to the second step in adjusting for selection bias. To do this, we add functions of these estimated probabilities into the first stage individual-level regressions used to calculate regression adjusted average city-industry wages. For movers, we add a quadratic of the probability that an observationally similar individual was born in a given state and was observed in a given city and a quadratic of the probability that an observationally similar individual stayed in their birth state. For stayers, we add a quadratic of the probability that an individual remained in their state of birth. For immigrants, we add a quadratic of the probability that an similar individual was observed in a given city in the preceding Census year. Dahl allows the coefficients on these functions to differ by state, whereas we assume that they are the same across all cities.
