## Abstract

A low-quality patent system threatens to slow down the pace of technological progress. Previous estimates based on litigation studies suggest that the majority of patents granted by the U.S. patent office should not have been issued, giving credit to concern about low quality. This paper proposes a new way of measuring patent quality. The methodology is based on twin patent applications granted at one office but refused at another office, and we apply it to the five largest patent offices. The results suggest that quality in patent systems is higher than previously thought, although the U.S. patent office performs weakly.

*Keywords:* inventive step, non-obviousness, patent quality, weak patent

## 1. Introduction

Concern that the patent system inhibits rather than encourages innovation has become a staple of the business and technology press (*e.g.*, *The Economist*, 2015). A major source of concern is that patent offices may grant too many low-quality patents, whose existence can chill the R&D investment and commercialization processes, either because of background uncertainty about freedom to operate or because of implicit or explicit threats of litigation.

Concern about patent quality is by no means new. The recent *Economist* article quoted itself from 1851 saying that the granting of patents “begets disputes and quarrels betwixt inventors, provokes endless lawsuits [and] bestows rewards on the wrong persons.” But in the last few decades, significant increases in the number of patent applications granted and the frequency of patent litigations, as well as media attention such cases have received, have given these concerns new force in the academic literature. Major patent offices are well aware of the problem and several of them have initiatives underway aimed at improving the quality of patent review. For example, the U.S. Patent and Trademark Office (USPTO) now has an Office of Patent Quality Assurance and has recently initiated an ongoing online ‘patent quality chat.’<sup>1</sup>

We interpret concern about low-quality patents as corresponding to concern that patents are being granted whose inventive step is too small to deserve patent protection. Conceptually, there are two pathways by which this may be occurring. A first source of low quality in patent system relates to the fact that patent offices might *apply systematically a standard that is too lenient*, relative to some conception of optimal stringency. Some of the discussion of the patent quality problem, particularly in the United States, has this flavor. Jaffe and Lerner (2004), for example, argue that changes in the incentives of the USPTO, the U.S. courts, and U.S. patentees over the 1980s and 1990s led to a systematic lowering of the standard for a U.S. patent grant.

A conceptually distinct source of low quality in patent system is mistakes—*granting patents that in actuality do not meet the office’s own implicit standard*, however high or low that standard may be. Observers of the patent system also discuss this issue. For example, Lemley and Shapiro (2005:83) write: “There is widespread and growing concern that the Patent and Trademark Office issues far too many ‘questionable’ patents that are unlikely to be found valid based on a thorough review.” Although there are clear patentability requirements and patentable subject matters, flaws in the examination process (Meurer, 2009; Lemley and Sampat, 2012; Frakes and Wasserman, 2014; Nagaoka and Yamauchi, 2015) and in the governance of patent offices (de Saint-Georges and van Pottelsberghe, 2013; Picard and van Pottelsberghe, 2014) affect the quality of the examination process. More generally, the grant decision rests ultimately on a subjective comparison of the

---

<sup>1</sup> See <http://www.uspto.gov/patent/initiatives/patent-quality-chat>

application's inventive step and the office's standard for novelty. Perfect consistency of decision-making seems unlikely to be the outcome of such a process.

The practical and normative consequences of these different sources of low quality are different. Systematically low standards create monopoly power and transfer rents in situations where the triviality of the invention arguably does not justify the reward. But low standards consistently applied are not, logically, a source of uncertainty about which patents are truly valid. Such uncertainty only comes about if standards are not applied consistently. Scholarly literature refers to mistakenly granted patents as 'weak' patents and shows that the litigation threat that they pose reduces welfare by leading consumers to pay supra-competitive prices due to the public good nature of challenging a patent (Farrell and Shapiro, 2008; Encaoua and Lefouili, 2009; Choi and Gerlach, 2016).

We propose a formal model that attributes inconsistent patent examination decisions across offices to differences in office thresholds or mistakes by one or another office. We then use novel data on multiple examination outcomes for the same invention in different patent offices to estimate the magnitude of these sources of inconsistency. Our data are derived from a population of about 400,000 inventions with linked patent applications that have been examined in at least two of the five major patent offices, covering in total more than a million applications. The premise of our model is that a refusal by an examiner in one jurisdiction raises doubts with regard to the legitimacy of the patent grant secured elsewhere. In particular, we estimate a statistical model of the grant process that captures parametrically the effects of different grant standards in different countries, the effect of observable application attributes on the grant probability, and the possibility of personal (*i.e.*, examiner) discretion in every decision. The estimated parameters are then used to quantify the height of the inventive step and the prevalence of weak patents.

To foreshadow the results, we find that differences across offices in the threshold appear to be quantitatively more significant than within-country inconsistency of decisions, but such inconsistency is present to varying degrees across countries. The model estimates imply that only 2–6 percent of granted patents have dubious validity in the specific sense that they appear to be inconsistent with the country's own standard for patent grant (what we call weak patent). An additional 2-15 percent can be thought of as low-quality in the sense that they would not have been granted if the patent standard of some other country had been applied. The inventive step threshold appears to be lowest in China and the United States, and highest in Japan. While these estimates are of interest in their own rights, given the difficulty in measuring patent quality, they also inform policy discussion. In particular, our results have important implications for current international agreements between patent offices and for discussions about how to fix the patent system.

The rest of the paper is organized as follows. Section 2 presents background discussion on patent quality. Section 3 presents the empirical strategy and Section 4

presents the data. Sections 5 and 6 discuss the econometric results and robustness tests, respectively. Section 7 concludes.

## 2. Background

Most of the existing literature looks at the issue of low quality by measuring the fraction of litigated patents that are found by a court to be invalid. Such studies provide valuable insights on the prevalence of invalidity. It is unclear, however, how invalidation in court relates to the two possible sources of invalidity. If one assumes that the courts are implicitly applying the same standard as the patent office, and that courts make perfect decisions, then a court invalidity finding corresponds to a case in which the office did not correctly apply its own standard. In practice, it is also possible that the court is applying a more stringent standard—and that it makes mistakes. Thus, litigation studies tell little about the quality of the examination process or the size of the inventive step threshold.

Patent litigation studies report ‘invalidity’ rates in the range between 30 to 75 percent. Allison and Lemley (1998) reviewed final validity decisions of 299 litigated patents and found an invalidity rate of half. Cremers *et al.* (2014) report that about 30 percent of appealed patent suits have their initial decision overturned. Furthermore, European patents, with the same set of claims, that are litigated in multiple courts can differ in their court outcome. Zischka and Henkel (2014) affirm this high rate of uncertainty and find a 75 percent invalidity rate of appeals at the German Federal Patent Court between 2000 and 2012. These studies suggest that invalidity rates might be quite high. However, given that a mere 0.1 percent of patents are litigated to trial (Lemley and Shapiro, 2005), such patents are not a random sample of the population, so it remains unclear what these statistics tell us about the overall prevalence of invalidity.

Recognising this problem, Miller (2013) attempts to correct for selection into an invalidity hearing. Using 980 adjudicated and 1960 control patents at the USPTO, he estimates a population-wide invalidity rate of 28 percent. However, the selection into Miller’s sample is twofold: selection into a patent being disputed, and selection into parties choosing trial over settlement. The first selection is not accounted for, suggesting that the 28-percent figure may still be biased, though the direction of bias is unclear.

As illustrated by the litigation studies, the basic approach to assessing the level of quality in the system is to investigate what happens when another qualified decision maker (but ideally many) takes a fresh look at the question of whether an asserted invention qualifies for patent protection. As far as we can ascertain, the only academic study in that vein that does not rely on litigation data is Paradise *et al.* (2005). The authors manually examine the validity of 1167 claims of 74 U.S. patents on human genetic material. They find that 448 claims (38%) were problematic. The ‘second-pair-of-eyes review’ program at the USPTO, which began in the year 2000 but has been discontinued since, aims at assessing

examination quality by re-examining a random set of patent applications. However, data are not publicly available and Allison and Hunter (2006:737-8) comment that this review is a “subjective, in-house process metric guided by no apparent standards that may fall victim to unconscious bias or external influence.”

In contrast with these studies, Palangkaraya, Jensen and Webster (2011) use a revealed behavior method to estimate rates of patent invalidity. They analyze the population of all 34,000 patent applications that were granted by the USPTO and examined at both the EPO and JPO during the 1990s. Assuming that the number of forward citations at the USPTO is a proxy for the correct decision, they estimate that 6.1 and 9.8 percent of patents are, respectively, incorrectly rejected and incorrectly granted.

### 3. Empirical strategy

Our research seeks to implement the second-pair-of-eye approach with a much larger set of inventions and with more pairs of eyes. Our context allows each patent office to have its own implicit standard, and every decision-maker to make mistakes. We do so by analyzing the grant outcome of ‘twin’ patent applications submitted to multiple jurisdictions. Twin applications are applications covering the same technical content in different jurisdictions.<sup>2</sup> We estimate an index of the probability that each patent application is granted under the differing circumstances of the different patent offices, and then use the resulting estimates to predict the inventive step threshold and the proportion of weak patents. The sample for the analysis is the population of 408,133 inventions described in patent applications filed between 2001–2005 in at least two of the EPO (European Patent Office), the USPTO, the JPO (Japanese Patent Office), the KIPO (Korean Intellectual Property Office) and the SIPO (State Intellectual Property Office of China). We use this time period in order to ensure that the applicant has had a chance to pursue protection in as many countries as she chooses, and to allow sufficient time to reach a grant decision. These five offices, known collectively as the ‘IP5 Offices’, attract about 80 percent of worldwide patenting activity.<sup>3</sup>

We employ a reduced-form model of the patent examination decision to separate any systematic factors related to the particular office from the examiner decision about the specific application. Our model of the actual examination decision assumes that each invention has a unique but unobservable inventive step ( $c_i$ ), and this inventive step is therefore shared by all of the applications to different offices. The probability of granting patent application  $i$ , by an examiner in office  $j$  is a function of this inventive step  $c_i$  (invention fixed effect); the office-specific inventive step threshold required for a grant ( $\tau_j$ );

---

<sup>2</sup> Because applicants must submit twin applications to foreign jurisdictions shortly after the submission of the priority filing (up to 12 or 31 months after), the decision to submit twin applications is not driven by the (revealed) grant decision in the office of priority. There is thus no selection on actual grant outcome.

<sup>3</sup> There were 1,821,150 patent applications filed worldwide in 2010 (priority plus second filings). Of these, 1,452,925 (79.8%) were filed in the IP5 offices (PATSTAT Autumn 2014 version).

a set of covariates ( $\mathbf{x}_{ij}$ ) capturing observed heterogeneity at the patent-office level (e.g., differences in the number of claims, filing route); and examiner specific factors that are not systematic to the office. These factors combine to give an index,  $y_{ij}^*$ , which maps into the probability of a grant for each application in each office.

We do not observe this index but rather the binary grant decision,  $y_{ij}$ , which takes the value 1 if invention  $i$  is granted a patent at office  $j$  and 0 otherwise. We estimate  $y_{ij}^*$  using a latent variable approach:

$$y_{ij}^* = -\tau_j + c_i + \mathbf{x}_{ij}\boldsymbol{\beta} + \varepsilon_{ij}, \quad y_{ij} = 1 [y_{ij}^* > 0] \quad (1)$$

where a patent for invention  $i$  is granted at office  $j$  if the latent score is greater than 0. From (1) it can be easily seen that  $(-\tau_j + c_i)$  is the extent to which the content of the application surpasses the office inventive step and that  $\mathbf{x}_{ij}\boldsymbol{\beta}$  represents the influence of other systematic features of the office's examination rules.<sup>4</sup> We start by assuming for simplicity that the individual elements of parameter vector  $\boldsymbol{\beta}$  are constant across  $j$ 's. In concrete terms, this means that the effect of, e.g., the number of claims on the latent score is common across offices. We will relax that assumption at a later stage.

The stochastic error term  $\varepsilon_{ij}$  is the aggregation of factors that makes the decision on the criteria for patentability uncertain (i.e., subjective). It captures all of the reasons why, after allowing for the systematic tendencies captured by the regressors, different examiners might reach different decisions on the same invention. That is, if the same application were examined in the same office, under the same office procedures but by a different examiner, any difference in the decision would be explained by  $\varepsilon_{ij}$ . Conceptually, if invalidity is only a minor issue, then most of the differences in outcomes at different offices would be due to systematic office effects; in our model this would correspond to the variance of  $\varepsilon_{ij}$  being small. Conversely, a large variance, causing outcomes across offices to differ even after controlling for invention and office attributes, would be evidence that one or more offices are granting weak patents. An implicit identifying assumption is that  $E_j(\varepsilon_{ij}) = 0$ , i.e., examiners at office  $j$  take correct decisions<sup>5</sup> on average. (Any systematic deviation from the 'correct' outcome is captured by the office-specific component.) Likewise  $E_i(\varepsilon_{ij}) = 0$ , i.e., every invention is treated fairly on average across offices.

We then use the model parameters to tease out the sources of inconsistency in the grant decisions across offices. We call  $\widehat{y}_{ij}$  the correct (i.e., predicted) grant outcome and  $y_{ij}$  the observed grant outcome. The inconsistency is composed of patent applications that are

---

<sup>4</sup> We are aware that there are several reasons why patent offices deny a grant. However, a low inventive step (similarly, too obvious invention) is by far the most common reason for refusal.

<sup>5</sup> In other words, the number of type I errors is equal to the number of type II errors. Relaxing this assumption would lead to slightly higher rates of weak patents for some offices (not reported).

granted at one office but where the equivalent is refused by at least one other office. Conceptually, one can decompose the two key quality dimensions (inventive step threshold and weak patents) into three components: office inventive step threshold difference; focal office ‘mistake’; and other office ‘mistake.’ Patents mistakenly granted at the focal office are what we call weak patents. In practice, we compute the components in the following way:

- (a) the grant is ‘correct’ given the focal office’s inventive threshold but
  - (i) the other office(s) made a mistake given that their ‘correct’ decision should be to grant the application (‘Other office mistake’);
  - (ii) the other offices(s) were correct in deciding a refusal (‘Office threshold differences’);
- (b) the grant is ‘incorrect’ given the focal office’s inventive threshold (‘Focal office mistake’, regardless of what the other offices’ decisions should have been).

We illustrate these various cases in Section 5.

#### 4. Data and variables

##### 4.1 A dataset of one-to-one equivalents across offices

The construction of the dataset is a major undertaking. It combines data from seven offline and online sources. The main data source is the EPO-OECD PATSTAT database (October 2014 release) for the backbone of the dataset. We start from the universe of priority patent applications filed anywhere in the world over the period 2001 to 2005 (de Rassenfosse *et al.*, 2013) and track their one-to-one equivalents in any of the five offices.<sup>6</sup> A priority filing is the first patent application describing an invention. Application  $P_B$  in country B is a one-to-one equivalent of application  $P_A$  in country A if  $P_B$  claims  $P_A$  as sole priority (*i.e.*, no merged patent applications) and  $P_A$  is only claimed by  $P_B$  in office B (*i.e.*, no split patent applications). In this sense,  $P_A$  and  $P_B$  cover the same technical content and are ‘twin’ applications. We also extract from PATSTAT information on applicants’ country of residence, patents technological fields as identified with the International Patent Classification (IPC) codes, and filing route (either the ‘Paris Convention’ route or the PCT route).<sup>7</sup>

Data on the application legal status (granted/refused/withdrawn) come from: the EPO’s INPADOC PRS table for PATSTAT for European and Chinese applications; from JPO’s public access on-line Industrial Property Digital Library Database (IPDL) for Japanese applications; from KIPO public access on-line IPR Information Service (KIPRIS) for Korean applications; and from the USPTO’s Public Pair on-line database for US applications.

---

<sup>6</sup> Thus, our sample may include a priority patent application filed, say, at the Brazilian patent office and with an equivalent at the EPO and the USPTO.

<sup>7</sup> The ‘Paris Convention’ route is the traditional filing route for patent applications (sometimes call the national route). The term PCT stands for ‘Patent Cooperation Treaty.’ It is an international treaty that facilitates international patenting.

Data on the number of claims of published patent applications come from: PATSTAT for European applications; SIPO's on-line patent search platform for Chinese applications; IPDL for Japanese applications; KIPRIS for Korean applications; and lens.org for US applications. We developed specific web-crawlers to collect online information.

#### 4.2 Variables

Our main dependent variable,  $y_{ij}$ , is the binary outcome that takes the value of 1 if patent application  $i$  was granted by an examiner in patent office  $j$  and 0 if refused.<sup>8</sup> Our measure of refusal includes applications that were examined and refused by the patent office plus all quasi-refusals. Quasi-refusals include patent applications that were withdrawn at the EPO following a negative search report containing X or Y citations, which challenge the inventive step of an application. Indeed, many applications at the EPO are withdrawn after a (negative) office communication, which Lazaridis and van Pottelsberghe (2007) take as evidence of quasi-refused applications.

There are three observable sources of heterogeneity with respect to the grant outcome in the data: systematic office differences ( $j$ ), systematic invention differences ( $i$ ), and application-patent office differences ( $ij$ ). The first two sources are accounted for by the use of office and invention fixed effects, respectively. Concerning the third source, we control for four variables,  $x_{ij}$ , that are likely to induce heterogeneity in the grant decision across offices for the same invention.

The first of these controls is a dummy variable, *local applicant* $_{ij}$ , which equals 1 if there is at least one applicant with an address in the same jurisdiction as the examining patent office, and 0 otherwise. There is clear empirical evidence that patent offices give differential treatment to applications based on the country of residence of applicants, with domestic applicants having a higher probability of grant (Webster, Palangkaraya and Jensen, 2014). This home bias may reflect prejudice, but it may also reflect the fact that domestic applicants have stronger incentives to push the patent application in their home market or that they may be more familiar with their home patent system.

The second is the dummy variable *priority filing* $_{ij}$ , which takes the value 1 if application  $i$  is a priority filing in office  $j$  and 0 otherwise. By the construction of our data, there can be only one priority filing per family. Firms usually file a priority filing in the office they know best, which may affect the likelihood that they receive a grant in that office. The country of the priority office may also be the most important market, where incentives to push for a grant are stronger.

---

<sup>8</sup> In reality, there is a spectrum of possible examination outcomes. In particular, an application may be granted but have some of its claims denied in one or more offices. We have not explored the empirical significance of this possibility. Differences in languages of the patent documents across offices make such an approach challenging to implement in a large scale.

The third is the dummy variable  $PCT_{ij}$ , which indicates whether the patent application was filed through the Patent-Cooperation Treaty route.<sup>9</sup> There are non-trivial administrative implications of using the PCT route that may affect the consistency of examination outcome (*e.g.*, search report shared between all the offices, extension of priority right from 12 to 31 months).

Finally, we control for the number of claims ( $claims_{ij}$ ), which is the number of claims articulated in the patent application at the time of lodgment. Although twin applications in our sample cover the same technical content, there might be slight differences in the construction of the applications across offices. The number of claims is a proxy for these differences.

Table 1 presents a summary of the characteristics of the patent applications at each office for two samples. The balanced sample (Panel A) is composed of 10,822 inventions for which a patent application has been filed at all five offices (there are thus 54,110 patent applications). The full sample (Panel B) is composed of 408,133 inventions with a patent application in at least two offices, covering in total more than a million applications. Overall, on the full sample, the JPO, at 72.2 percent, recorded the lowest grant rate and the SIPO, at 96.3 percent, the highest. More than half of applications at the JPO had at least one local applicant compared with only 3.1 percent at SIPO.<sup>10</sup> SIPO had also the smallest rate of priority filings and JPO the highest. (Indeed, except for the EPO, there is a strong correlation between the office of priority filing and whether the applicant is local to that office.) Use of the PCT was highest for the EPO but lowest for KIPO. Finally, the average number of claims at the time of application varies between 10.3 at the JPO and 17.8 at the USPTO.

**Table 1. Descriptive statistics**

|                                 | N       | Grant (%) | local applicant (%) | priority filing (%) | PCT (%) | claims |
|---------------------------------|---------|-----------|---------------------|---------------------|---------|--------|
| <i>Panel A. Balanced sample</i> |         |           |                     |                     |         |        |
| EPO                             | 10,822  | 84.9      | 27.7                | 6.3                 | 44.2    | 14.7   |
| USPTO                           | 10,822  | 91.5      | 17.5                | 18.6                | 33.0    | 17.2   |
| KIPO                            | 10,822  | 88.3      | 14.7                | 14.6                | 4.5     | 14.9   |
| JPO                             | 10,822  | 82.6      | 36.5                | 36.7                | 37.7    | 11.1   |
| SIPO                            | 10,822  | 97.9      | 0.6                 | 0.6                 | 21.7    | 15.2   |
| <i>Panel B. Full sample</i>     |         |           |                     |                     |         |        |
| EPO                             | 163,012 | 76.8      | 44.2                | 9.8                 | 45.3    | 15.6   |
| USPTO                           | 325,068 | 91.4      | 20.0                | 22.3                | 22.8    | 17.8   |
| KIPO                            | 127,314 | 84.4      | 41.5                | 41.0                | 2.3     | 14.9   |
| JPO                             | 278,760 | 72.2      | 56.3                | 56.4                | 26.5    | 10.3   |
| SIPO                            | 170,777 | 96.3      | 3.1                 | 3.3                 | 19.7    | 15.3   |

Notes: Data relate to patent applications filed between 2000 and 2005. See main text for data sources.

<sup>9</sup> Note that some equivalents are filed partly through the PCT route and partly through the Paris route, leading to within-twin variation.

<sup>10</sup> The low proportion of local applicants at the SIPO reflects the fact that very few Chinese firms apply for patent protection in foreign jurisdictions, which is a pre-condition for being in the sample.

Table 2 provides an overview of the number of equivalents (*i.e.*, twins) between offices. There are 125,704 direct equivalents between the USPTO and the EPO. The lowest number of equivalents is reached between the EPO and the KIPO (32,082 patent applications) and the highest number is reached between the USPTO and the JPO (212,673 applications). As far as the SIPO is concerned, it is most integrated with the USPTO, followed by the JPO.

**Table 2. Cross-country number of equivalents**

|       | EPO     | USPTO   | KIPO   | JPO     | SIPO |
|-------|---------|---------|--------|---------|------|
| EPO   | -       |         |        |         |      |
| USPTO | 125,704 | -       |        |         |      |
| KIPO  | 32,082  | 87,228  | -      |         |      |
| JPO   | 91,878  | 212,673 | 79,757 | -       |      |
| SIPO  | 59,597  | 119,841 | 64,925 | 113,561 | -    |

Notes: Data relate to the full sample.

## 5. Estimations and results

### 5.1 Inconsistency rates

We start by examining the data by looking at the ‘raw’ inconsistency rates, *i.e.*, without correcting for office-specific differences and without neutralizing the influence of examiners’ subjective assessments. Results presented in Table 3 for the full sample of patent applications show that 21.3 percent of the patents that were granted by the EPO were refused in at least one other office. The corresponding figure is highest at the SIPO, where 26.9 percent of patents granted were refused at least once elsewhere and lowest at the JPO, with a rate of 13.9 percent.

**Table 3. Inconsistency rates**

| Office | Number of granted patents | Proportion refused elsewhere |
|--------|---------------------------|------------------------------|
| EPO    | 125,195                   | 21.3                         |
| USPTO  | 297,072                   | 25.2                         |
| KIPO   | 107,501                   | 25.7                         |
| JPO    | 201,335                   | 13.9                         |
| SIPO   | 164,527                   | 26.9                         |

Notes: Data relate to the full sample.

However, as discussed, some of the rejections observed certainly are well founded. The proportion of patents refused elsewhere reflects a combination of legitimate inventive step threshold differences, mistakes by the focal office and/or mistakes by at least one other office. Next section teases out these sources of heterogeneity.

### 5.2 Econometric decomposition of the inconsistency rates

There are two conceptually distinct ways to estimate equation (1) econometrically. The first considers that we observe *different outcomes of the same unit  $i$* . The patent examination process is subject to office-specific rules, incentives and biases, and these unobserved factors may or may not be correlated across offices. For example, inventions based on new technologies may be harder to assess against the examination manuals and, therefore, it may be more appropriate to assume  $cov(\varepsilon_{ij}, \varepsilon_{ik}) > 0$  if  $j \neq k$ , that is, the omitted explanatory factors for each invention are correlated across offices. Such an approach treats equation (1) as a system of  $J$  linear equations that one can estimate with a seemingly unrelated regressions (SUR) model. The SUR model has the advantage of taking into account the correlation of errors across offices in the estimation process to improve the efficiency of the estimates. However, implementing fixed effects in a SUR model is not straightforward when the number of individual effects is large. One can control for fixed effects by demeaning the data but at the cost of dropping one equation due to the additivity constraint introduced (leading to a singular variance matrix problem). In addition, the SUR model requires a balanced dataset, which considerably reduces the size of the sample we can use.

The second way considers that we observe the *same outcome in different contexts  $j$* , leading to a fixed-effect (FE) panel data model. The fixed-effect estimator handles unbalanced panels and produces estimates for all offices, which are two desirable features over SUR. However, it does not account explicitly for the fact that the decision errors may be correlated across offices. The extent to which this limitation matters for the present study is an empirical question. As we show below, the SUR and FE models produce quantitatively similar results—our preferred specification is thus the FE model.

Finally, note that we rely on a linear probability model, which implies that some predicted probabilities might lie outside the unit interval. This issue is of little concern because we are interested ultimately in *ranking* patents by their probability of being granted (and not in the predicted probability score of the grant rate *per se*). In addition, most of the covariates are discrete such that the linear assumption is acceptable. However, we correct standard errors by using heteroskedastic-robust standard errors when appropriate.<sup>11</sup>

We first present results of the econometric model, and then discuss the sources of apparent inconsistency. Table 4 presents the coefficients of equation (1) estimated with different regression models and samples. The column labeled M1 presents an estimate of the SUR model performed on the balanced sample of inventions, having equivalent patent applications at all five offices. As discussed, we need to exclude one office for the model to

---

<sup>11</sup> An alternative estimator is the conditional (*i.e.*, fixed effect) logit estimator. However, it does not exploit information from patent families that are granted or refused at all offices, which is not desirable. Should we use the conditional logit estimator, we would not be able to predict a value for the all negative/all positive outcomes. That is, the predictions we would obtain would be conditional on observing an inconsistency.

run, and we arbitrarily exclude the EPO. Column M2 presents results of the fixed-effect estimator for the balanced sample and column M3 for the full sample of inventions with equivalent in at least two jurisdictions. Coefficients in models M1–M3 are constrained to be equal across offices ( $\beta$ ). In model M4, the coefficients for each covariate are office-specific ( $\beta_j$ ), but we only report coefficients for the base group (EPO) for conciseness. Finally, model M5 extends model M4 by controlling for the timing of the decision by offices. The reference group is the office that published the grant (or rejection) decision first.

**Table 4. Determinants of grant outcome**

|   | M1                 | M2                 | M3                 | M4                  | M5                  |

Notes: \* p < 0.001; heteroskedastic-robust standard errors in models M2–M5; <sup>(a)</sup> iterated seemingly unrelated regression with demeaned data; <sup>(b)</sup> office-specific coefficients, but only coefficients for the reference group (EPO) reported.

A first observation is that coefficients have similar magnitude and statistical significance between the SUR model (M1) and the FE model (M2). A second observation is

that extending the analysis to the full sample (from model M2 to model M3) produces coefficients that have similar signs but that have stronger statistical significance (expectedly). Notice the strict probability threshold of 1 per thousands for declaring statistical significance of estimated parameters in order to account for the large number of observations. Regarding specific covariates, the results suggest a strong *local applicant* effect, similar to that documented in Webster, Jensen and Palangkaraya (2014). In model M3, the *local applicant* effect is double the magnitude of the *priority filing* effect, and the *local applicant* effect is biggest for non-priority filings. Note that the *priority filing* effect is negative at the EPO (reported in columns M4 and M5) but positive at the other offices (not reported). Patent applications filed through the *PCT* route have a grant rate that is about 3–4 percentage points higher than non-PCT applications (models M1–M3). The effect of the number of claims is always negative, but statistically significant only with the full sample (models M3–M5). Finally, the timing of the decision has a strong effect on the probability of grant, with later decisions being systematically less favorable.<sup>12</sup> (Note that we cannot control for the nature of the decision because such variable is correlated with the unobserved invention fixed effect.)

Next, we use the estimated parameters of model M5, the most complete model, to tease out the sources of apparent inconsistency in a variance decomposition exercise. As explained, we first need to compute the ‘correct’ grant outcome  $\widehat{y}_{ij}$  for all patent applications in our sample. The grant outcome is based on the linear prediction of the latent quality score (including the fixed effect). Since the linear probability model minimizes the mean squared errors, it produces correct inferences on average. This implies that the number of type I errors (mistakenly refused applications) is equal to the number of type II errors (mistakenly granted applications). Hence, patent applications with a predicted latent quality score above the  $g_j$ ’s percentile must be granted, and refused otherwise—where  $g_j$  corresponds to the average observed grant rate for applications at office  $j$ .<sup>13</sup> We then break down the raw inconsistency rate as explained in Section 3.

Let us illustrate the methodology using the EPO as the focal office. According to Table 3, 21.3 percent of applications granted at the EPO (=26,624) have been refused in at least one other office. We present each of the three cases in turn. First, there are 8.5 percent of applications that were legitimately granted by the EPO and legitimately refused by at least another office (‘Office threshold difference’). Second, there are 8.8 percent of applications that were legitimately granted by the EPO but unduly refused by at least another office (‘Other office mistake’). Third, a total of 4 percent of applications were

<sup>12</sup> There are two potential reasons for this negative effect. The order of decision could reflect the amount of prior art available to assess the patentability of the invention. In that sense, offices that give a decision later have potentially more prior art available (identified by other offices) to refuse a patent. It could also reflect offices’ own judgment about the patent, knowing that it takes longer to refuse a patent application than to accept one.

<sup>13</sup> It is easy to verify that this condition implies that the number of type I errors equals the number of type II errors.

unduly granted by the EPO. Regardless of whether other offices made a mistake in the applications (in terms of unduly *refusing* an application), these cases correspond to a ‘Focal office mistake’ and represent what we call weak patents.

**Table 5. Correct and incorrect grant at the EPO**

| Other office(s)<br>decision = refusal | EPO decision = grant                        |   |               |
|---------------------------------------|---|---|---------------|
|                                       | <i>Incorrect grant</i><br>(% total granted) | <i>Correct grant</i><br>(% total granted) |               |
| <i>Correct refusal</i>                | 3,472 (2.8)                                 | 10,633 (8.5)                              |               |
| <i>Incorrect refusal</i>              | 1,504 (1.2)                                 | 11,015 (8.8)                              |               |
|                                       | 4,976 (4.0)                                 | 21,648 (17.3)                             | 26,624 (21.3) |

Using this method, we can decompose the number of inconsistent grants from Table 3 into the various components for all offices. Doing so leads to the figures presented in Table 6.<sup>14</sup>

**Table 6. Decomposition of inconsistency rates, model M5**

|       | Raw rate<br>(Table 3) | Reason(s) for inconsistency    |                                |                         |
|-------|-----------------------|--------------------------------|--------------------------------|-------------------------|
|       |                       | Office threshold<br>difference | Focal office<br>mistake (weak) | Other office<br>mistake |
| EPO   | 21.3                  | 8.5                            | 4.0                            | 8.8                     |
| USPTO | 25.2                  | 15.4                           | 4.0                            | 5.9                     |
| KIPO  | 25.7                  | 10.6                           | 4.8                            | 10.3                    |
| JPO   | 14.0                  | 2.1                            | 5.7                            | 6.2                     |
| SIPO  | 26.9                  | 15.3                           | 1.6                            | 10.0                    |

Notes: The first column corresponds to the last column of Table 3. See main text for details.

Overall, differences in office threshold account for up to about 15 percent apparent inconsistency at the USPTO and the SIPO and 2.1 percent at the JPO. In other words, the JPO has the highest threshold and the USPTO and the SIPO the lowest. Mistakes at the focal office (*i.e.*, rate of weak patents) account for as little as 1.6 percent at the SIPO and as much as 5.7 percent at the JPO.

The pattern of low grant thresholds is as would be expected. Japan, the country with the highest threshold according to the parameter estimates in Table 4, has a very low rate of granting patents that would be refused by other countries; China has the highest.<sup>15</sup> Of course, we cannot say what is the ‘right’ standard, so these numbers cannot be strictly

<sup>14</sup> The results presented in Table 6 consider that the local inventor effect induces legitimate office differences in the grant outcome. Assuming that the local inventor effect is a mistake increases the focal office mistake by a maximum of 0.2 percentage points.

<sup>15</sup> In theory, the strictest office should have a value of 0 in the column *Difference in office threshold*. The actual number differs from 0 due to the influence of patent-patent office factors ( $x_{ij}$ ).

interpreted in terms of patent quality. But they do give some quantitative perspective on the possible significance of low thresholds.

It is tempting to compare the rate of weak patents between offices and conclude that the Chinese patent office is the most 'accurate' office, since it has the lowest figures by this measure. However, bear in mind that these figures correspond to *absolute* rates of weak patents, and that one must take into account the fact that offices have varying grant thresholds. In the limit, if an office has an extremely low threshold such that all applications should be granted, it can never make a mistake in the form of granting a patent that it should not have. Conversely, offices with very high thresholds have more room for making mistakes. One can normalize the figures by estimating how much the office decision deviates from a random decision-making using the observed grant rate. For example, knowing that the observed grant rate at the EPO for the full sample is 76.8 percent, a random grant decision would produce 17.8 percent of Type I and Type II errors ( $0.768 \times (1 - 0.768)$ ). Relative to the total proportion of granted patents (0.768), the invalidity rate of random decisions would be simply  $1 - 0.768 = 0.232$ . Since the estimates imply that the EPO made 'only' 4.0 percent of Type II errors, its relative accuracy is  $0.232 / 0.04 = 5.8$ . The interpretation is straightforward: should the EPO take random grant decisions, it would grant 5.8 times as many weak patents as it currently does. That is, the rate of weak patents is about 17 percent of the random error rate for the EPO. The relative accuracy rates at the other offices are 2.15 (USPTO), 3.25 (KIPO), 4.8 (JPO) and 2.3 (SIPO), which implies that the EPO and JPO are the most accurate offices and the USPTO and SIPO the least accurate.

## 6. Discussion and robustness tests

### 6.1 Accounting for differences in patentable subject matters

Although the empirical analysis controls for four covariates that are likely to induce heterogeneity, one potential source that is not accounted for is the difference in patentable subject matter across jurisdictions. Such differences would lead to a legitimate grant at one office and a legitimate refusal at another office, but according to our method above, would be interpreted as an error in one office.

We know from discussions with patent attorneys that the definition of patentable subject matter in mechanical engineering is very similar across jurisdictions. Hence, we can use the field of mechanical engineering to get an estimate of focal office errors that is not affected by difference in patentable subject matter definition.

Table 7 assigns each family to one or more major technology OST technology groups based on any one of the IPC subclasses given at any office.<sup>16</sup> In addition, we use the 'Biotechnology' and 'Software' classifications from the OECD (2003) and Graham and

---

<sup>16</sup> Office of Science and Technology, UK classifications.

Mowery (2004) respectively. Table 7 breaks down the inconsistency rates by technology field. The estimates are based on model M5, that is, the fixed effect estimator with office-specific coefficients run on the full sample and controlling for the timing of office decision.

**Table 7. Proportion of weak patents by technology fields, model M5.**

|                               | EPO        | USPTO      | KIPO       | JPO        | SIPO       |
|-------------------------------|------------|------------|------------|------------|------------|
| Electrical                    | 5.3        | 4.2        | 4.2        | 5.8        | 1.8        |
| Instruments                   | 4.4        | 4.0        | 5.1        | 5.6        | 1.7        |
| Chemicals & pharmaceuticals   | 3.1        | 6.3        | 6.0        | 7.2        | 1.6        |
| Process engineering           | 3.5        | 5.0        | 5.4        | 6.1        | 1.4        |
| <b>Mechanical engineering</b> | <b>3.0</b> | <b>3.3</b> | <b>5.4</b> | <b>4.9</b> | <b>1.2</b> |
| Biotechnology <sup>†</sup>    | 3.7        | 7.3        | 6.3        | 7.9        | 2.6        |
| Software <sup>††</sup>        | 6.4        | 6.3        | 4.7        | 7.7        | 2.2        |

Notes: An application can be allocated to more than one major technology groups based on multiple IPC subclasses assigned in any office. Major OST group excluding Biotechnology and Software. <sup>†</sup>Based on OECD (2003). <sup>††</sup>Based on Graham and Mowery (2004).

One can read the results in Table 7 in two ways. First, if one believes that differences in patentable subject matter across offices affect the estimates presented in Table 6, then one should only focus on the estimates for the field of mechanical engineering. The rates of weak patents are slightly lower than those presented in Table 6 but the ranking across countries is globally consistent. Thus, concerns that differences in the patentable subject matters may drive results seem misplaced. Second, if one believes that there are no major differences in patentable subject matters across offices for applications in our sample, then the estimates can be taken as reflecting differences in rates of weak patents across fields.<sup>17</sup> Qualitatively, every office has a relatively high rate of weak patents in software, and every office other than the EPO has a relatively high rate in biotechnology. This is loosely consistent with the notion that subjective judgment about inventive step is harder in these newer fields.

## 6.2 External validity

Patents applications in our sample are considerably less selected than in litigation studies previously used to study invalidity. Compared to previous studies, the sample does not select on likely (in)validity or on invention quality. Our sample does, however, select on invention economic value, because applicants are more likely to pursue protection in multiple countries for more valuable inventions. Although patent value is not a patentability requirement, we cannot exclude the possibility that economic value may be correlated with inventive step and we therefore investigate the extent of selection in the data.

<sup>17</sup> We do not expect to find that many focal office mistakes are traced to differences in patentability subject matter as the bulk of our IP5 sample are experienced applicants who would not file patent applications in jurisdictions where the subject matter was not patentable.

A first selection that might occur is selection on quality with respect to the filing decision, that is: Are higher quality inventions more likely to be filed abroad (and hence more likely to appear in our sample)? One way of testing for the presence of selection at office  $j$  involves estimating equation (1) for all offices but  $j$  and assessing whether the recovered invention fixed effect (*i.e.*, estimated inventive step) predicts filing at office  $j$ . Table 8 reports the mean value of the fixed effect thus computed by filing status at each office. In the first row, we obtain the invention fixed effect by estimating equation (1) with ignoring EPO observations. We then compute the mean score of the fixed effect by filing status at the EPO. Overall, the results suggest that quality does affect the filing decision, with higher quality patents being more likely to be filed in foreign jurisdictions.

The last column of Table 8 reports the marginal effect at the mean of a one-standard deviation increase in quality on the filing decision. For instance, a one-standard deviation increase in invention quality leads to a 3.7 percent increase in the probability that a patent application will be filed at the EPO. Selection is strongest at the USPTO and weakest at the EPO. Thus, it appears that our sample is biased to a small but not trivial extent towards inventions with higher than average inventive step.

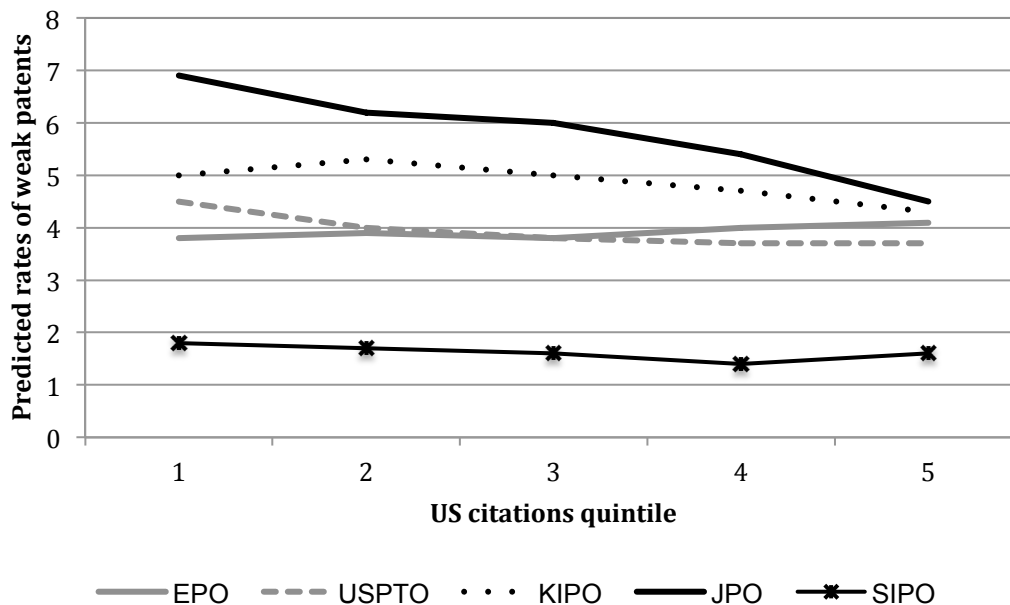

**Table 8. Invention quality by filing status**

|       | Not filed | Filed | $\Delta$ | Marginal effect |
|-------|-----------|-------|----------|-----------------|
| EPO   | -0.019    | 0.016 | -0.035*  | 0.037           |
| USPTO | -0.121    | 0.045 | -0.165*  | 0.115           |
| KIPO  | -0.025    | 0.030 | -0.055*  | 0.052           |
| JPO   | -0.042    | 0.021 | -0.062*  | 0.064           |
| SIPO  | -0.042    | 0.053 | -0.096*  | 0.087           |

Notes: Columns 'Not filed' and 'Filed' report the mean score of the invention fixed effect and ' $\Delta$ ' is the difference. \*:  $p < 0.001$ .

The fact that inventions in our sample are somewhat selected on their quality does not tell us anything directly about possible bias in our estimates. We assess the effect of quality on the rate of weak patents by relying on a commonly used quality indicator, namely the number of forward citations. As recently reviewed by Jaffe and de Rassenfosse (2016) there is a long tradition in the literature of using forward citations to proxy the technological merit of the invention (Albert et al., 1991; Narin, 1995; Trajtenberg, Henderson and Jaffe, 1997). Figure 1 presents the relative rates of weak patents by quintiles of citations received at the USPTO. We count citations received by USPTO patents from USPTO patents up to seven years after first publication using the PATSTAT database (de Rassenfosse, Dernis and Boedt, 2014:402). Overall, the proportion of weak patents seems to decrease with the number of citations received, especially at the JPO, where rates of weak patents go down from 7 percent to less than 5 percent.

**Figure 1. Proportion of weak patents by citations received**

Notes: 0 citation for the first quintile; Q2: 1 citation; Q3: 2 or 3 citations; Q4: 4 or 5 citations; Q5: 6 citations or more.

Summarizing the insights from both tests we come to the following conclusions. Selection into filing at the EPO is small and the effect of quality on the rate of weak patents is stable across quintiles of the quality metric. Therefore, the population-wide rate of weak patents is likely to be around 4 percent. A similar reasoning holds for the KIPO, with a population-wide rate of weak patents of about 5 percent. There is strong selection into filing at the SIPO but the rate of weak patents is fairly stable across quintiles of the quality metric such that the population-wide figure is probably close to 2 percent anyway. In light of the strong selection into the filing decision at the USPTO, the population wide rate of weak patents is probably closer to 5 percent than 4 percent. At the JPO, population-wide rate is probably closer to 7 percent than 5 percent for similar reasons.

### 6.3 Sensitivity to applicant experience

We next investigate whether the consistency of grant outcomes varies with the level of experience of applicants. On the one hand, more experienced applicants are presumably better equipped to push their patents through the examination process, leading to less mistakenly granted patents. On the other hand, more experience applicants may invest less energy in each application, leading to potentially more heterogeneity in grant decisions.

**Figure 2. Proportion of weak patents by applicant experience**

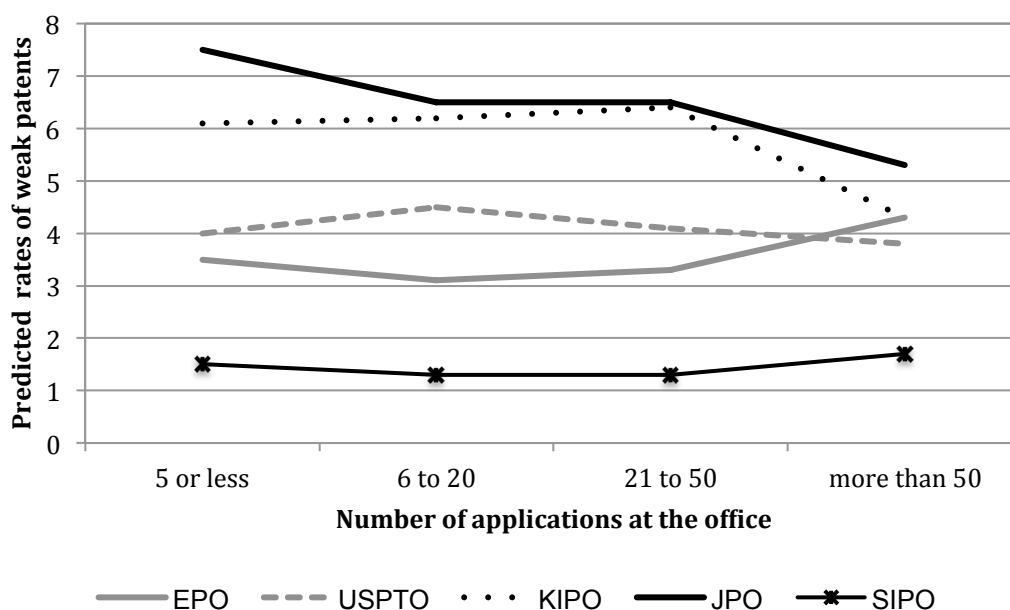

Figure 2 depicts the rates of weak patents by applicant experience (measured in terms of the number of applications submitted to the focal office over the whole study period). Overall, no clear pattern emerges.

#### 6.4 Additional considerations

We have also estimated model M5 on the subsample of 322,583 applications with the same number of claims across jurisdictions in an attempt to further control for unobserved heterogeneity. Doing so gives qualitatively similar results (not reported).

Finally, there is some question about whether the PATSTAT database correctly records all Japanese language PCT applications to the JPO that were refused. We find no evidence that these applications are missing from the central PATSTAT file. However, to accommodate the possibility that these applications are erroneously tagged as pending, we recoded as 'refused' all Japanese applicants who filed at the JPO through the PCT but have no recorded legal status. This amounted to 36 applications and did not change the results.

## 7. Conclusion

There is significant concern around the world that patent offices are issuing patents that should not have been granted. Studies based on litigation outcomes suggest that this problem is quantitatively significant, with the overall fraction of dubious patents ranging from a quarter to three-quarter of all patents. Our analysis of patent applications examined by multiple offices around the world suggests that the overall prevalence of low-quality patents is likely to be smaller.

We model the patent grant process in a way in which imperfect decision-makers compare their assessment of the quality of an invention to an internal standard of quality necessary for grant. This method allows us to decompose differences in the decisions of multiple decision-makers into those that are due to a mistake by the first decision-maker, those that are due to a mistake by subsequent decision-makers, and those that are due to differences in the standard applied by different decision-makers. The kind of decomposition that we have undertaken requires repeated observations on each invention and each decision-making unit.

Our analysis of about 400,000 inventions considered for patent protection by multiple patent offices suggests that all three sources of inconsistent decisions are important. The strength of our analysis is to compare various offices using the same data. To push the point, it allows us to conclude that differences in grant outcomes are primarily driven by policy choices, in the form of different inventive step thresholds, rather than poor implementation of the inventive step thresholds, *i.e.* the granting of weak patents.

Specifically, we find that the fraction of weak patents—those that should not have been granted given the offices own grant threshold—does not exceed single digits for any office. Having noted this, we find that some offices are better at screening patent applications than others. Our data suggest that the examiner decisions at the USPTO and the SIPO are two times more accurate than a random decision, whereas the EPO and the JPO are five times more accurate.

While the sample used for the analysis is large, it is not randomly drawn. Patents examined in multiple international jurisdictions are likely to be of higher economic value than the average patent. Our analysis of the selection problem suggests, however, that rates of weak patents for the population of all applications to each office are unlikely to be much higher than our estimates for this IP5 sample. Thus, even allowing for selection bias, our results suggest rates much lower than the rates found by litigation studies.

The (much) lower rates of weak patents obtained with our methodology compared to litigation studies are not surprising, for four reasons. First, litigated patents are highly selected towards those most likely to be found invalid. Second, litigation studies implicitly assume that courts apply the same standard as that of the office whose grant is being reviewed, and do not make mistakes themselves. In practice, it is possible that courts systematically apply a stricter standard for validity than the patent office—and make mistakes themselves. Third, although patent applications in our sample are examined by up to five examiners from very different cultures and language groups, every examiner spends considerably less time than if the patent were re-examined in litigation. Finally, review by a court is fundamentally different from review by another examiner because the court review is an adversarial proceeding. It is possible that there is prior art that no patent examiner will ever find, but which the adverse party is able to bring to the court's attention. Using survey

data in Germany, Henkel and Zischka (2015) provide evidence that parties often provide new prior art to the court. Thus overall our results provide a different perspective on patent quality and should be viewed as complementary to those of litigation studies rather than directly comparable.

The fraction of patents that might be said to be low quality in the sense that they result from systematically low inventive step thresholds is larger than the rate of weak patents, ranging from 9 percent for the EPO to approximately 11 percent for Korea and 15 percent for the United States and China. Even these larger numbers seem modest relative to the general policy discussion about the problem of patent quality. This suggests some notion that all of these offices have a grant standard that is too low relative to some normative judgment. Our analysis—based as it is on comparing decisions across offices—sheds no light on that issue.

While we believe that our explicit model of the grant process is a valuable contribution, we also note that the simple rates of across-office inconsistency in Table 3 suggest strongly that population-wide invalidity rates of 25% or more are implausible. This reinforces the suggestion above that much concern about patent quality reflects normative judgments that standards are too low, rather than invalidity in the sense of the granting of patents that do not meet the existing standard.

These findings are interesting in their own right in light of concerns about patent quality, but they also contribute to current policy discussions on patent prosecution highway (PPH) agreements. PPH designates a set of initiatives for providing accelerated prosecution procedures by sharing information between patent offices. Our results show that there is considerable heterogeneity across offices. The PPH agreements intend to increase the harmonization of decision. However, they may also propagate a wrong decision into the whole patent family, further weakening patent rights. Our results further illustrate that some offices are more accurate than others, which may create additional tensions in the context of PPH agreements.

The magnitude of the difference between the figures presented in this paper and the figures obtained using patent litigation data bear important implications for discussions about patent quality. One difficulty in interpreting the difference is that we do not know how much of it might be due to selection bias in the litigation studies. But if we assume for the sake of argument that invalidity in the view of the courts is truly significantly higher than invalidity in the view of the offices, we can make four general points. First, much of the debate around quality focuses on improving examination. Our results suggest that this effort is somewhere between misguided and only marginally useful. Second, some of the debate has a flavor of the U.S., in particular, having a low threshold. Our results suggest that while it is true that the U.S. threshold is somewhat low, raising it to the level of the highest country would have only a modest impact. Third, more generally, there is a general tone to

the debate that the uncertainty around validity is the PTOs' fault. Our results suggest rather that it is inherent in the examination process that a non-trivial number of invalid patents will be approved. Finally, we bring into sharp focus the question of *why* courts are more likely to invalidate than examiners. To the extent that it is because of the adversarial nature of litigation, the finding brings the question of how to best to organize re-examination processes that are undertaken within offices. But if it is because judges are fundamentally tougher than examiners, the finding raises deeper questions about administrative law, since judges are not supposed to apply different standards.

Our analysis is silent on the optimal level of ambiguity. On the one hand, weak patents hurt businesses and may slow down the pace of technological progress. On the other hand, ensuring high quality examination is costly, especially in light of the fact that the majority of patents have limited economic potential. Future research should investigate whether delivering more harmonized outcomes for businesses is likely to improve welfare. Our results provide a useful starting point in that regard.
